The amebæ in man now recognized are *Entameba coli,* a harmless commensal, *Entameba histolytica,* and *Entameba buccalis.* These last two are pathogenic forms. *E coli* is 10 to 20 microns in diameter when free, grayish in color, spheroidal, sluggish, and has a distinct nucleus and only one vacuole. *Entameba histolytica* is larger, irregular, greenish yellow, and has a distinct nucleus and many vacuoles. *Entameba buccalis* I take to be identical with *E. histolytica,* its habitat bringing about an apparent difference, if any. Amebic cysts containing spores enter the mouth through contaminated water, fruits, vegetables, etc., and pass to the large intestine. Here they may set up an acute necrosis with its sequelæ, or may remain apparently latent, infecting the whole system.

This latest condition may for a long time present no clinical symptoms, but the amebas may be found in the stools, urine, and in the serous cavities of the body—abdominal, pleural, pericardial, synovial, tooth sockets, etc. It is this tooth socket necrosis we are dealing with, and why this socket necrosis should be more common than that in other localities is apparent when we consider the action and function of the teeth, trauma produced by biting hard substances, tartar, their septic location, etc.

Treatment here will be practically the same as that for amebic dysentery, modified only as the location will permit. And from what I have said one will see the fallacy of any purely local treatment unless that local treatment should also act systematically.

Ipecac or its active principle, emetine, is good, and should always be tried. Concerning the use of this Bass and Johns[2] advise that the mouth be rinsed once a day (at night) with a solution of fluid extract of ipecac or of emetine, by forcing the solution back and forth between the teeth. The solution should be made up just before use

by adding one or two drops of fluid-extract of ipecac, or one or two drops of a solution of 5 grains of emetine in one ounce of water, to half a glass of water. If ipecac or emetine is used constantly as a mouth wash in this manner, it is doubtful if the individual would ever contract the disease. It has struck me that if this drug or its active principle, in the proper dose, be added to chewing gum, it might serve a good purpose to the afflicted jaw-waggers in the early stage.

"Scaling or scraping the roots of the teeth: If a tooth surrounded by a pyorrhea pocket is extracted and examined, considerable accumulation of deposit of various kinds is found on the part of the root that was between the level of the edge of the gum and the edge of the remaining peridental membranes. This may be either soft or hard. There is a deepset opinion held by the dental profession that it is important to scale or scrape this off to facilitate healing. This might be true if there was any hope that the destroyed peridental membrane would be regrown and again cover the root of the tooth where it formerly existed. We have not the slightest evidence, however, that such a thing can occur. Apparently, therefore, the only benefit that would result would be what results from cleanliness and removal of foreign material.'"

For this purpose I have found that the occasional use of cream of tartar on one's brush will cause this tartar to release its hold and give better results with less trauma than anything I have yet tried. However, that we have to handle our cases intelligently, know the action of our drug and give it to get that action is well portrayed by Jepps and Meakins[3] of the British Medical Research Committee in examining soldiers returning from the Mediterranean region, suffering from irritable heart. Sixty-five cases were examined, 24 were found to be *Entameba histolytica* carriers. The treatment here was emetine bismuth iodide, carried out by the employment of the drug in three different ways. When given in a powder, this drug causes nausea and vomiting, so it was administered in tablets and pill form and was either mixed or coated with some material supposedly insoluble in the stomach. In all 23 courses of treatment were given with these preparations. No nausea or vomiting was produced, but in eight cases severe diarrhea and abdominal cramps occurred. Some looseness of the bowels was observed in all cases where the drug appeared to have any action. In the treatment with the stearin-coated tablets, there were eight out of twelve cases treated, or 66 per cent. With the second, the stearin-coated pills with resin ointment basis, there were no cures, while with the third, another form of stearin-coated tablets, there was only one cured out of four cases treated, or 25 per cent. Then the emetine bismuth iodide was given in cachets of 3 grains each to eleven cases. Ten cases, or 91 per cent., were cured after twelve daily doses. Jepps and Meakins found as the result of this detection and treatment that (1) additional infections with intestinal protozoa may be detected at the sixth and later examinations. (2) Infections of *E. histolytica* in which no cysts measuring over 10 microns in diameter are found in the stools are far from uncommon. (3) The use of emetine bismuth iodide has cured a large proportion (95 per cent.) of the amebic dysentery carriers. (4) The best method of administration of this drug is in the form of the loose powder in cachets in daily doses of 3 grains; at least 36 grains should be given in all. (5) Symptoms of irritable heart in amebic dysentery carriers are reduced in a large number of those patients who have been cured of the amebic infection. (6) Infection with intestinal protozoa has no marked effect on the differential leucocyte count.

Another drug and one that I have had much experience with in common with many other physicians of South Texas and Mexico, a drug which we conider as much a specific for amebic infection as we do quinine for malaria, is *Chapparro amargosa*.[5] It may be of interest here to state that this drug was first brought to the notice of scientific physicians in 1884 by J. L. Putegnat, a druggist of Brownsville, Texas. He observed the natives, after running the gauntlet of the medical man, for intractable bowel troubles, would invariably find relief in this drug. He had an abundant opportunity to try it out on the U. S. soldiers stationed at Fort Brown, made for them decoctions and infusions with such universally good result that his product succeeded in getting quite a local reputation. Even to-day it is not uncommon for soldiers who have returned from the Philippines and the Canal Zone, infected with amebas to send for this drug, the men having had the accepted treatment.

(4) This drug has an active principle, a glucocide, isolated by Putegnat and called by him amagosin. There is no doubt that this drug, *Chapparro amagosa*, needs to be studied anew, and if the clinicians in active practice are any criterion, it would prove more efficacious than ipecac. The likelihood of not getting a pharmacologically active product, I really believe, is the reason we are so slow in having this product accepted. The native Mexicans make an infusion or decoction, which with them is best. A fluid extract is now to be had, and this, combined with a digestant, agrees better with the stomach. Given in teaspoonful doses, three or more times a day, it will bring results that will surprise the most skeptical.

Transmission of Lepra by the Mosquito.—Suarez de Figueroa refers to the cumulative incidence of leprosy in certain localities on the Catalan coast in Spain. The culex, anopheles and stegomyia mosquitoes are all prevalent here and malaria is common. In certain areas only the culex could be found, and it is precisely here that one finds no leprous foci. Otherwise stated the anopheles and stegomyia, one or both, could be an agent in transmitting lepra, even as they are known to transmit other diseases. Every other possible cause of lepra may be excluded.—*Gaceta Medica Catalana.*

Military Medicine.

ADRENAL INSUFFICIENCY IN THE COMBATANTS.

Much has been written on this subject from various viewpoints during the past year or two. In the *Journal de Médeeine de Bordeaux* for July, Carle expresses himself to the following effect: The syndrome of Addison's disease is the result of slow, progressive destruction of these bodies. The symptoms fall under five heads: (1) Lumbar and lumboabdominal pains; (2) brown pigmentation of the tegumentary structures; (3) a variety of circulatory disturbances; (4) digestive disorders, which comprise anorexia and vomiting; (5) progressive asthenia, which culminates in somnolence and dread of movement. As a consequence of these symptoms the patient soon succumbs, developing a cachectic state before death. When the pericapsular sympathetic plexus or the adrenals themselves are involved secondarily in other processes, as tubercle or malignant disease, the same condition develops.

The mechanism is readily understood in these secondary cases of Addison's disease, because the glands are destroyed outright; but this destruction is not a *sine qua non* for the supervention of the syndrome, which may occur as a functional manifestation. In acute infectious diseases during the period of convalescence, as a sequel of chloroform anesthesia, after antityphoid inoculation and the exhibition of salvarsan, we see the syndrome develop, and not insidiously, but suddenly and brutally. All of the symptoms of Addison's disease are recognizable, but in a different setting. One subject may show incoercible vomiting, with or without diarrhea, and abdominal pains. Low blood pressure, or somnolence and prostration, may dominate the scene. According to the particular grouping of symptoms, these cases may be confounded with cholera or acute poisoning or acute peritonitis.

Out of all this confusion the syndrome of acute adrenal insufficiency has been isolated, and distinguished clinicians have elaborated it. Next in order, the abortive syndrome demands our attention, this often being grafted upon other disease pictures. We see evidences of it in pregnancy. The author even goes so far as to state that symptoms of toxemia of pregnancy belong here—the pigmentation, vomiting, etc. In ordinary pulmonary tuberculosis, without reference to localization of the process in the glands, the same picture may assert itself.

The so-called "war addisonian" is a subject *sui generis*. His malady is not directly associated with any of the preceding syndromes. As a rule, he has undergone shell shock. The symptoms are chiefly abortive, and perhaps not readily recognizable at first. The expression may be a dyspepsia—a disgust for food, and vomiting. It is perhaps the presence of the white line of Sergent or the striking improvement which follows adrenalin injections, which gradually suggests the adrenal motivation. In the opinion of many clinicians the response to adrenalin is the acid test in the diagnosis of these states. A psychasthenic state may also exist, due purely to adrenal insufficiency. It stands in some relationship to the general asthenia, which is one of the most characteristic manifestations of this insufficiency. Another manifestation is myasthenia of the same origin. Now and then these abortive cases may pass into full-fledged adrenal insufficiency. Of thirteen cases especially studied, two were examples of total and the rest of abortive insufficiency. The antecedents of these patients showed great variety. In the midst of much confusion the asthenia and low-blood pressure always stand out prominently. It seems reasonable to conclude that these abortive states are due to functional overtaxing of the organs, and that after a prolonged rest the subject will have recovered his equilibrium. The facts thus far bear out this view.

Constipation in the Army.—The recent literature of this important subject seems less than its importance warrants. In *La Presse Médicale* for July 25 Labbé considers it very thoroughly. Despite the great prevalence of diarrheic and dysenteric cases in the army, the constipated outnumber them, and Labbé holds that of the two classes of enteric disturbance constipation is the more serious, which is saying much. The prevalence of constipation is the result of factors which differ considerably from the causes of constipation in civil life. The diet of the soldier is notably deficient in vegetables and fruits, to which even the poorest civilian has access. The second factor is no less significant—the soldier often lacks opportunities to defecate. Moreover, he is quite unable to resort to laxatives and enemata. Labbé makes four forms or rather degrees of constipation, viz., simple, spastic, atonic, and toxic. The simple form is expressed by the usual symptoms of retention, such as discomfort, bad taste, coated tongue, loss of appetite—all of which vanish after a movement. In the spastic form the patient may not know that he is constipated, because he may pass some fecal matter daily, but he really retains a large amount and there is a good deal of local and reflex disturbance. Since the retention is due to spastic contractions of the colon, the condition is more or less inveterate and does not improve after the use of laxatives and enemas. Different in type is atonic constipation, for here fecal impaction may go on indefinitely if artificial relief is not obtainable. In this form there is often partial intestinal obstruction and much meteorism may result. The fourth or toxic form may follow both the spastic and atonic types. There may appear to be a serious affection of the general health, a failure of nutrition, but the most careful exmination fails to discover anything beyond constipation. In a specimen case the chief symptom was crises of vomiting, while a second patient, in addition to nausea and vomiting, had a notably cachectic look and was extremely emaciated. These subjects appear to present symptoms which have a cyclical evolution, as if the organism was able to disburden itself of toxic material at stated intervals. The author also recognizes a form of constipation in which colitis is a sequela. So-called stercoral typhlitis causes symptoms of chronic appendicitis, but the appendix does not necessarily participate in the process.

The treatment of constipation in the soldier is a matter of vital importance, because obviously we cannot speak truthfully of a prophylaxis which

can apply to all troops. If the men can get whole wheat bread, legumes, and fruits the problem will, of course, be vastly simplified. If there is a lack of latrines the installation of a plentiful supply will prove of immense value. Toilet paper must always be supplied in abundance. Some of the men who have not good habits of defecation can, of course, profit by personal hygiene along these lines. The best way to overcome simple constipation is by agar or mineral oil and one may drink cold water on rising, while tobacco often acts as a laxative. Of drugs for internal use castor oil and salines are the best. These are often of value in daily laxative doses. The good results of belladonna in constipation are probably due to its favorable action in spastic cases. Other antispastics like valerian have some value. Strychnine acts well in the atonic form and in recent years suprarenal extract and glycerophosphates have been used with benefit. If autotoxemia is present the patient is placed on a non-putrefying diet and given intestinal antiseptics.

Malaria in the Army.—Lieut.-Col. E. J. Williams writes in the *Canadian Medical Association Journal* for June, 1918, on the treatment of malaria in the British army. He says that while the question as to the absolute cure of malaria by the administration of quinine, arsenic, and other drugs is still unsettled, one thing is certain, viz., to prevent a recurrence of the malarial symptoms of a patient a systematic prolonged course of treatment is necessary. The form of quinine best suited to combat the disease, the length of the period over which the treatment shall be continued, the procedure adopted for the carrying out of the treatment are matters worthy of consideration. Quinine has long been recognized as the one drug which acts most favorably upon the plasmodium of malaria. The value of the drug is enhanced by the addition of arsenic in the majority of cases. The tablet or powder form has not proven as efficacious as the solution with sulphuric acid. The sulphate of quinine in the acid solution is the most commonly employed form for administration by mouth. However, in some cases where the desired effect is not obtained the hydrochloride or the bihydrochloride in solution has been given with better results. The dose of the sulphate is from 20 to 30 grains daily, of the hydrochloride or bihydrochloride 7 to 15 grains. The intramuscular method has met with better results, on the whole, than that by the mouth. Still abscess formation at the site of injury is not uncommon, and thus this method does not meet with general favor. The bihydrochloride is used, the dose being from 5 to 10 grains. The intravenous method is without doubt the most efficient one when ordinary care and skill are employed, and is practically devoid of danger. The action of the drug is much more rapid and the amelioration of the symptoms more marked than in the other forms of administration. Five to seven grains are given in 200 to 300 c.c. of physiological saline solution, once or twice a day. In severe cases 30 grains may be given in twenty-four hours. In malignant cases and especially those of the cerebral type, this is the only form of administration which seems to produce any appreciable effect. The administration of arsenic in addition to quinine is advisable in practically all cases. The length of period over which the drug should be administered is estimated differently by different authorities, some advising a daily use for three months, others intermittent dosage over a period of from 12 to 18 months. In the experience with the troops in the East for two malarial seasons, the recurrence of attacks during the second summer in those who had suffered from malaria during the first season was so common that in the opinion of Williams the twelve months' period of treatment seems to be the minimum.

Use of Caustic by Simulators.—The ingenuity of the simulator is proverbial, and to produce artifacts, the nature of which he so little comprehends, using, like the old masters, so few utensils, and often deceiving the elect, strikes the medical man as remarkable. It is not the lesions but the peculiarities of incidence that usually unmask the malingerer. In an article in *La Presse Médicale* for May 30, Minet considers the effects of actual caustics—acids and bases. The simulator usually applies the caustic solution with a pledget of cotton or a brush over a circumscribed area of skin. The sharp even definition of the margin has therefore come to suggest the artifact. Sometimes he dips a finger or joint in the solution and the "glove finger" effect may also betray him. Minet has never known a simulator to immerse his whole hand in caustic, and this conservatism betrays at times, for the simulator controls his injury, or at least tries to do so. The caustic substance is often revealed by the appearance of the lesion—it may be silver nitrate, sulphuric acid, nitric acid, hydrochloric acid, caustic potash, caustic soda, or the mixture known as copper water, which contains oxalic and sulphuric acids. One familiar with these burns has little trouble in determining the causal solution. The crude simulator may explain his injury as caused by a contusion or other trauma.

The practice of provoking abscesses by the hypodermic injection of turpentine or benzine has been extended to caustics. As a result a simulator appears with a peculiar lesion on the forearm or hand which is ultimately recognized as a beginning slough. If one looks a little beyond the periphery he will find the telltale needle puncture. The sphacelus presents a red areola. If the affected tissues are incised blood or other fluid does not escape. There is an odor of gangrene. As the slough separates the surrounding tissues have become edematous. At this period the lesion shows no evidence of its subepithelial origin; no one would believe that the caustic had not been applied directly to the integument. But the needle puncture, the reaction in the cellular tissue—not seen in the superficial lesion—and the contour of the sphacelus which is distinctly polycyclic, serve to differentiate it. Phlegmon is a complication or sequel and the expulsion of the slough usually exposes the tendons, muscles, and ligaments. Pus may burrow. The simulators explain these lesions by invoking mechanical injuries or claiming that they are the result of blood poisoning following slight punctures, and they exhibit at times considerable ingenuity as liars.

Official Announcement Regarding the Volunteer Medical Service Corps.

The following is addressed to Executive Committees and County Representatives of the Volunteer Medical Service Corps and State Committees of the Council of National Defense:

No official or committeeman representing the Volunteer Medical Service Corps or the General Medical Board of the Council of National Defense is now authorized or has been authorized to favor any organized or unorganized method of coercion in inducing members of the medical profession to join the Medical Corps of the Army or Navy, or the Volunteer Medical Service Corps. Our committeemen are especially urged against favoring any movement that would threaten to impair a medical man's standing in his local, state or national society because he refused to enroll in the Army or Navy, or the Volunteer Medical Service Corps.

It must be made clear that the Volunteer Medical Service Corps is a volunteer organization which has for its object the enrollment and classification of the profession. Its members are entitled to wear an insignia which will clearly indicate that they have offered their services to the government, when such services are needed. Patriotism cannot be created by coercion. It also must be made clear that the Volunteer Medical Service Corps has for its primary object furnishing its classification to the Army, the Navy, the Public Health Service, the Red Cross and Provost Marshal, as well as to civilian institutions and communities, as a guide in providing for their needs to the best advantage.

The object of the Corps is not to disturb any medical man in the performance of any duty to which he has been assigned by any governmental agency either for service at the front or at home.

(Signed) Edward P. Davis,
President, Volunteer Medical Service Corps.

Franklin Martin,
Chairman, General Medical Board, Council of National Defense.

Influenza in the Army and Navy.—For the week ended September 20, the Surgeon General's office reported a death rate of 4.4 per cent., compared with 2.3 per cent. the preceding week. This increase was attributed in large measure to influenza, but these figures do not show the seriousness of the situation since the disease had been greatly on the increase since that time. The total for all camps, on September 27, was 42,367 cases. Pneumonia cases showed a slight decrease, 717 new cases being reported, compared with 723 the preceding day. The situation at Camp Devens, Mass., seems to be coming under control, the number of cases reported daily being on the decrease. The number of pneumonia cases also shows a decrease, though thus far since the outbreak of the epidemic there have been 81 deaths from pneumonia. At the Great Lakes Naval Training Station, 8,475 cases of influenza have been reported, but they have been mostly mild in character, only 77 deaths having occurred. The epidemic in Camp Dix, N. J., is also subsiding. On September 28, 2,677 new cases of influenza were reported to the Surgeon General's office from the various camps. While it is believed that the crest of the epidemic has been passed in the Eastern camps, it is expected that the disease will spread westward, and that there will be an increased mortality in the Western camps during the next few weeks. It is reported that tests have been carried out in the army camps with a serum which has been found to be an almost sure preventive of pneumonia. It is stated that this serum is now being manufactured in quantities sufficient to treat 50,000 persons daily, and that only one injection is sufficient to afford protection. Strict quarantine is being enforced at all army camps for the present.

Nutrition Section Studies Army Rations.—Officers of the Nutrition Section of the Surgeon General's office are studying the army diet in the various army camps in the United States and France, as well as in the trenches. Twenty-nine officers of the Nutrition Section have been sent abroad, four of whom have been detailed to rest camps in England, where their knowledge of what the American soldier wanted and required was applied in a practical way. Reports on the observations will be made to the Surgeon General's office, together with suggestions for the better preservation and conservation of food in the camps.

Army Hospital at Saratoga.—George W. Pratt, State Conservation Commissioner, with the sanction of Governor Whitman, has offered the Federal Government sixty acres of the Saratoga Reservation as a site for an army hospital. Commissioner Pratt agrees to provide the plumbing system by which the medicinal waters may be carried to the hospital baths and to furnish the bottled waters to all the patients.

Surgeon General Gorgas May Be Retired.—It is reported, though without official confirmation, that Major General William C. Gorgas, who will reach the age of retirement next month, will probably be succeeded as Surgeon General of the army by Major General William M. Ireland. It is also rumored that General Gorgas will be recalled to active service, and assigned to the Inter-Allied Military Council in France.

Dr. Lucius P. Brown, Director of the Bureau of Food and Drugs of the New York City Health Department, has been granted leave of absence without salary for the period of the war and will shortly enter the army with the rank of captain. He will be in the food and nutrition division of the sanitary corps.

Deaths in the Service.—Lieut. Sidney Pearson Lewis of Jersey City, N. J., was killed by a shell on August 10, on the Somme battlefield, while serving with the Fifty-second Field Ambulance. Dr. Lewis entered the service last March, and after receiving his training at Fort Oglethorpe was transferred to the British Expeditionary Forces.

Capt. Rae Wygant Whidden, M. R. C., U. S. A., of New York City, died of pneumonia following influenza, contracted while serving at Camp Dix on September 25. He was a graduate of Harvard Medical School in 1911. Before entering the service he was visiting physician to Bellevue Hospital and assistant physician at the Presbyterian Dispensary. Captain Whidden was wounded during the bombing of a base hospital in France in 1917.

THE LIBERTY LOAN.

THIRTY thousand medical men have given up everything—practice, home life, ease, recreation, and in some cases life itself—for their country. There are over one hundred thousand of us left behind; some are physically unfit, some too old, some are in one way or another more useful here than they would be over there. Those of us who would go if we could—and that means at least ninety-nine out of every hundred—can make ourselves feel better by also making sacrifices by economizing, by pinching ourselves to the limit, and then buying bonds. Suppose each one of the one hundred thousand physicians still in the country bought only one thousand-dollar bond—and surely they could average that amount for a good investment—there would be $100,000,000, one-sixtieth of the entire amount of the loan taken by one-thousandth of the population. We have given more than our proportion of men to the army and navy, let the rest of us live up to our reputation, and for the honor of our profession buy more than our proportion of Victory bonds.

The business men of the country are contributing largely to the success of the Fourth Liberty Loan, not only by buying bonds but by advertising the loan. In this issue of the MEDICAL RECORD many of them have generously given space to the cause which they might have kept for advertising their own products. Our readers will note their names and not forget them in their future dealings.

SOME DIAGNOSTIC ASPECTS OF TYPHOID FEVER.

FROM the clinical standpoint, typhoid fever is a septicemia having a subacute evolution, initial symptoms of which are well known. The evolution and symptomatology of a normal typhoid are of such common knowledge that the affection is readily diagnosed, but there are many exceptions to this rule. There are certain processes which resemble typhoid fever very closely, such, for example, as acute miliary tuberculosis or the typhoid form of endocarditis, so that the diagnosis may remain in suspense until a laboratory examination settles the question.

But there are also types of typhoid which differ so greatly from the classical picture of the disease in the adult that their diagnosis is difficult, if not even impossible. Very frequently the early symptoms of typhoid are those of an ordinary infection, with headache and lassitude, so that the condition is supposed to be an infectious process due to any agent other than the bacillus of typhoid. And if among the symptoms of an ordinary infection a single symptom which ordinarily occupies the background, or may not even exist in an ordinary typhoid appears in the foreground and assumes a considerable intensity, the diagnosis may easily fail.

Many are the atypical forms of the early symptomatology of typhoid, among which may be mentioned a sudden commencement, more particularly met with in children, where the patient suddenly passes from a state of absolute health into the phase of full development of a typhoid, the period of incubation having passed by without offering any evidence of its presence. Chills, fever, headache, and vomiting suddenly supervene, so that typhoid is about the last disease thought of.

Pneumotyphoid, which comprises the pneumonias which mark the beginning of typhoid fever, the symptomatology of which is usually so intense that it overshadows the gastrointestinal phenomena, causes the clinician to overlook the true condition of affairs. Pleurotyphoid is characterized by the association of the general and functional signs of a normal typhoid with the physical signs of a pleurisy; but here the diagnosis should be a simple matter from the discordancy existing between the general signs and the local pleuritic signs. There are likewise the bronchotyphoid, with its violent initial bronchitis, and the pharyngotyphoid, with an angina as the primary manifestation. The nephrotyphoid type, with lumbar pain, albuminuria, hematuria, edema, and mild uremic symptoms, gives rise to the erroneous diagnosis of nephritis, until the temperature chart and rose spots indicate the true condition.

Finally, there is the typhoid beginning with meningeal phenomena, with symptoms of an ordinary meningitis, and only lumbar puncture, done at this time, will show the presence of the bacillus of typhoid in the cerebrospinal fluid, indicating the initial localization of the typhoid infection. The meningeal accidents are due to an infection of the meninges with the typhoid bacillus, either pure, or associated with the staphylococcus, pneumococcus, or tubercle bacillus, and these infectious meningitides have the same pathogenesis as the majority of the so-called primary meningitides; that is to say, they represent a meningeal localization of the bacteria which have, in the first place, invaded the organism by way of the circulation. In some instances a typhoid meningitis undergoing its evolution without the typhoid syndrome, has been diagnosed, while in others the meningeal syndrome has undergone its evolution during a typhoid fever

without giving rise to any changes in the cerebrospinal fluid and without the presence of any bacteria therein. The meningeal phenomena may arise toward the end of the third week during a confined typhoid, and here the differential diagnosis from the tuberculous form may offer considerable difficulty.

MONEY MAKES THE WAR GO.—Buy Liberty Bonds and speed it along.

ITALIAN SAVANTS AND ENDOCRINOLOGY.

SINCE the outbreak of the present war the Italian medical journalists, like the French and others, have shown their patriotism by citing the early labors of Italian scientists in various fields which have heretofore passed unrecognized. In *La Reforma Medica* for April 20, Ferraninni calls attention to the extirpation by Restelli in 1845 of the thymus gland and the record of the resulting symptoms as the first practical step in endocrinology. In 1879, Pellecani of Modena injected suprarenal extracts into animals, beneath the skin and into the peritoneal cavity, which was the first step in this direction since Brown-Sequard had shown in 1856 that these glands are essential to life. Pellecani was followed in this field by Foà in 1883. These two men brought to light many interesting biological facts.

One might, indeed, go back to Eustachius in this connection, for he described the adrenals minutely in 1563; and to Bartholinus, who in 1641 termed them the "atrabilious capsules," thus giving them a sort of endocrinous significance; and to Malpighi, who was the first to record their histology, in 1687. But this, of course, is another story. To return to the moderns, we find after Foà's work with suprarenal extracts, Ciaccio developing a histological technique based on differential staining of cell constituents, the consequences of which for endocrinology were far-reaching, inasmuch as the chromaffin granules were isolated. He was followed by an entire series of Italian investigations, and much detail was worked out in connection with the endocrine glands. A still more numerous Italian school were at the same time engaged in macroscopic studies; thus Ronconi covered the thymus, Cutelli the pineal body, Caselli the hypophysis, Pepere the parathyroid, etc., to mention only a few.

In 1889 De Dominicis was the first to extirpate the pancreas and cause experimental diabetes; while in 1892 Vassale began his well-known contributions on endocrinology. Although known chiefly in connection with the parathyroids, he did much work on the thyroid and hypophysis. In 1894-1898 Lo Monaco and others demonstrated the bone changes which follow extirpation of the thymus. Pende, who recently published a huge monograph on the internal secretions, was studying the ovary during this period, while Castellino at the same time investigated the relations between the endocrini glands and the autonomous nerves. In 1897 Rumms described geroderma, a type of endocrine dystrophy. Falta, Italian in name, but an Austrian, one of the leading endocrinologists, cannot, of course, be claimed in this connection. He was at work on endocrine dystrophies in the 90's, and has since published a large monograph which has been translated into English. The author of the review, Ferraninni, was also active in endocrine sympathetic research, and read a paper before the Academy of Sciences, Paris, as far back as 1890 on the therapeutic use of a gastric extract, while in 1887 he proposed pluroglandular extract treatment, although credit for this innovation is usually assigned to Renon and Deville, 1908. He showed also for the first time that hypotension can occur in arteriosclerosis. These names by no means exhaust the list, for numerous Italians have also done pioneer work in the less known glands and their extracts (spleen, parotid, etc.).

AEBLY'S CANCER STATISTICS.

RECENTLY, as noted in the MEDICAL RECORD, Dr. Aebly, a Swiss statistician, in analyzing the Freibourg cancer material by a new method, was able to show that the knife did not prolong the lives of cancer patients in the aggregate. These finds were evidently sufficient grounds for the substitution of irradiation for the knife at the clinic in question, although the latter course was probably decided on independently, because of the very small percentage of ten-year survivors found on tracing all of the material. The chief peculiarity of Aebly's method is that he traces the duration of the malady from the first appearance of the cancer, and not from the day of the first consultation. In the August 10 number of the *Correspondenz-Blatt fur Schweizer Aertze*, Labhardt, representing the operating surgeons, attacks Aebly's figures and conclusions. He does not attempt to answer him by statistical arguments, for the figures adduced seem to be final, but he insists that they hold good only for Kronig's material. If we glance over the latter's work, we shall see that he is an abdominal operator, pure and simple. Aebly does not know, or fails to take into account that Schauta had sixty ten-year survivors out of 219 vaginally operated cancers of the cervix. Labhardt has no ten-year figures at the Basle clinic, but he has 27 five-year survivors out of 165 women operated upon. Some of these have survived considerably more than five years, and he believes that there will be plenty of ten-year survivors. At Freibourg the exclusively abdominal intervention means a heavy primary mortality which cuts down in advance the ten-year possibilities. The author, in the interest of humanity, would maintain the original conception of the Winter propaganda that earliest possible intervention holds out the only hope for the cancer sufferer.

The rejoinder of Aebly to Labhardt's communication deals with the need of progress in cancer statistics. He concedes Labhardt's objections to the patient's word as to the duration of the malady, but he does not understand a reflection by the Basle Professor von Kronig for urging radium treatment for cancer, as if his motives were mixed. In regard to the suggestion that Kronig's clinic is not fairly representative of others, Aebly states that he has other figures to submit, and that his researches in cancer statistics have shown uniform results.

THE BULGARIAN BACILLUS couldn't grow in so foul a kultur medium. Let's sterilize it. Buy Bonds.

Radium Therapy in Hyperthyroidism.

Radium therapy has a wide field, and although divergences of opinion still exist as to its value there is little doubt that as a remedial agent its employment has largely increased. It has been employed for some years in the treatment of pathological conditions of the thyroid gland, more especially when pathological increase of function has ensued than when the gland has been merely enlarged. Dr. Albert Albe was the first to extend the field of radium therapy in this direction, and met with a considerable amount of success in the new field. Dr. W. H. B. Aikins of Toronto discusses the rôle of radium in the treatment of hyperthyroidism in a paper read by him at the meeting of the American Radium Society, held in Chicago, June 10, 1918, and published in the *International Journal of Surgery* for July, 1918. The writer has treated 45 such cases with radium, the majority during the past three years. Of these, 23 have been clinically cured; that is, the tachycardia, tremor, and restlessness have disappeared, and symptoms of excessive thyroid secretion have abated. In 17 cases there has been an improvement. The characteristic point in connection with the treatment was the relief of the nervous symptoms. In only a few of the cases did the gland diminish in size. However, the fact should be borne in mind that an operation would be necessary for this purpose, and that so long as the nervous symptoms persisted an operation would be a hazardous procedure. The merits of radium therapy in exophthalmic goiter, therefore, are that by relieving the nervous symptoms the operation for the removal of the goiter is robbed of one of its dangerous features.

IT MIGHT BE THE LAST CHANCE.—The rats are deserting the sinking ship. Bulgaria has gone; Turkey will be ready by Thanksgiving; Austria is Hungary; and as for Germany it's all bosh! Suppose the war were to stop suddenly and there were no more Liberty Loans, wouldn't the man who had no bonds feel pretty small?

Pneumonic Tendency of the Influenza Pandemic.

The ancient question as to whether pandemic influenza is air borne has naturally been asked in reference to the present visitation. In the *Correspondenz-Blatt für Schweizer Aerzte* for August 17, Lanz, a hospital physician, expresses the opinion that influenza is a contagious miasmatic affection, which spreads not only by contact but by air transmission. The air must become impregnated with germs, and then the uncertainty remains how far it can carry the infection and what is the viability of the microbe. The epidemic of 1889-90 tended to attack the upper air passages and the middle ear, while the present one is manifested as lobar and lobular pneumonia. The *x*-ray shows the implication of the hilus glands, and the pneumonia is largely of the pseudolobar, bronchopneumonic type and hence bilateral and very serious, with death following cyanosis and heart failure. Autopsy of previously healthy individuals shows the hilus glands as large as walnuts and bronchopneumonic foci. As a rule, there is no pneumonic sputum and no crisis; but the urinary chlorides are invariably decreased when the lungs are extensively involved, so that this test has considerable prognostic value. In the absence of specific remedies, physicians have gone back to the remedies of 1889—salicylate of sodium, infusion of digitalis, antipyrin, and codeine. In the direction of prophylaxis, Lanz suggests that patients should cough, spit, and sneeze into toilet paper, or similar substance, so that the latter can be burned. Turpentine fumes are recommended as a disinfectant for the respiratory passages.

The Wittenberg Thaler.

In the 16th century, in order to commemorate the arrest of an epidemic, perhaps of typhus fever, the good people of Wittenberg—it was when they really were good, worshipping not Gott, but God—had a coin struck off. On the obverse was a representation of the Crucifixion, with a biblical quotation, and on the reverse was the prototype of this, the serpent lifted up by Moses in the wilderness. This is known to collectors as the Wittenberger Thaler. A new Wittenberg Thaler is needed to commemorate the perfidity of Dr. Aschenbach and his cowardly crew of assistants who deserted their posts when typhus fever broke out in the prisoners' camp in that place two years ago. Let us buy bonds to serve as modern Wittenberg Thalers.

News of the Week.

The Influenza Situation.—During the past week the epidemic of "Spanish" influenza has spread through practically the entire country. Cases have been reported on the Pacific Coast, in California and Washington, and a few cases have been reported from Minnesota and Iowa. East of the Mississippi there are few States where the disease has not been found. The situation is most acute in the New England States, where the disease first made its appearance in epidemic form and where the death rate has been comparatively high. Boston has begun a concerted effort to stamp out the disease. The Executive Council in special session set aside $100,000 and created an Emergency Public Health Committee. The first step taken by this committee was to call on the American Red Cross at Washington for physicians and nurses to replace those who have died or become exhausted

by their arduous labors, the request being for 500 doctors and 1,000 nurses. With the help of the Army and Navy medical organizations and the Red Cross, it was expected that within twenty-four hours several hundred additional physicians and nurses would be available for service. The Massachusetts State Health Committee recommends that specialists, who can temporarily give up their practice, should register with the State Health Commissioner for service against the influenza epidemic. All unnecessary public assemblages have been dispensed with in Boston and the neighboring cities. The disease appeared suddenly in Norfolk, Va., on Monday, some 600 cases being discovered among workers in the Quartermaster depot there. In New York City the epidemic seems to be gaining momentum. The number of cases reported daily has gradually increased until, on September 27, 324 cases were reported. On this date the city registered its first 1,000 cases. Dr. Copeland, the Health Commissioner, made a request for $5,000 as a safeguard in combating the disease and the Board of Estimate gave him $25,000. This fund will be used in the employment of additional doctors and nurses. A resolution introduced into Congress by Senator Weeks of Massachusetts appropriating $1,000,000 for the Public Health Service campaign against influenza was adopted on September 28. The money will be expended in equipping hospitals and paying physicians and Red Cross nurses. It is reported from Boston that Dr. Timothy Leary of Tufts College has produced a curative serum which is said to possess remarkable efficiency. A preventive serum is stated to have been discovered by Dr. Park of the New York Health Department laboratory.

Naples Swept by Epidemic.—An epidemic of influenza is sweeping through Naples, Rome, Milan, and other Italian cities. Many cases are complicated by acute pulmonary conditions. It is estimated that in Naples about 100 deaths are being caused daily by the disease.

Garbage Plant Must Abate Nuisance.—Dr. Royal S. Copeland, Health Commissioner, has declared that the methods used by the Metropolitan By-Products Company, which conducts a garbage reduction plant on Staten Island, constitute a public nuisance. The company has been allotted five days in which to abate the nuisance, and unless it complies with this order the street cleaning department will be notified that no more garbage is to be taken to the plant. This is the outcome of a long and bitter fight which the residents of Staten Island have waged to force this company to modify its methods of handling garbage. As the plant is the source of a large part of the country's glycerine supply it is believed that a method of garbage reduction less objectionable to those residing in the vicinity than that at present employed will be devised which will admit of the continued operation of the plant.

New York City Curtails Work of Eye Clinics.—The New York City Department of Health has decided to curtail its clinical work on the eyes of children by suspending the fitting of glasses during the period of the war. This is purely a war measure and when the war ends there is no question that the clinics will be resumed. Clinic stations where the fitting of glasses has been the exclusive work will be closed, but other eye clinics where diseases of the eye are being treated will be continued.

Shortage of Guinea Pigs.—Because of the great shortage of guinea pigs a representative of the New York City Health Department has written to the Chief City Magistrate requesting him to urge the different City Magistrates to use their influence to induce any private institutions or persons who own guinea pigs to place them at the disposal of the health authorities and to make a vigorous effort to impress on the public the importance of guinea pigs for medicinal laboratory purposes.

Hospital Employs Women Ambulance Drivers.—Owing to the shortage of men ambulance drivers, the New York Hospital recently called on the women of the Motor Corps of the National League for Women's Service to drive the hospital ambulances until men can be obtained. Several women are now serving in this capacity.

North Atlantic Tuberculosis Conference.—Under the auspices of the National Tuberculosis Association a conference will be held in Pittsburgh, Pa., on October 17 and 18, at which the States of Delaware, Maryland, New Jersey, New York, Pennsylvania, Virginia, West Virginia, and the District of Columbia will be represented. Dr. Thomas McCrae of Philadelphia is the president. This year, at least, the conference will for the most part be devoted to the discussion of tuberculosis problems related to the war. After a year's additional experience in endeavoring to meet these problems the discussion will concern itself mainly with methods, concrete results to date, and definite measures needed for the future. Further information may be obtained by addressing Miss Alice Stewart, Bedford Avenue and Wandless Street, Pittsburgh, Pa.

The Malden (Mass.) Medical Society at its meeting on September 14 elected the following officers: *President*, Dr. L. F. McCarthy; *Vice-president*, Dr. C. H. Staples; *Secretary*, Dr. Samuel Hoberman; *Treasurer*, Dr. W. W. Kingsbury.

Obituary Notes.—Dr. William A. Hendryx of New York died suddenly in Allentown, Pa., on September 21, aged 69 years. He was a graduate of Rush Medical College and practised medicine for twelve years in Grand Rapids, Mich. During his residence there he became Lieutenant-Colonel in the National Guard. Dr. Hendryx became interested in mining and retired from the practice of medicine. He invented the cyanide process of separating metal from ore, as well as various types of mining machinery now in general use.

Dr. William Pickard Megrail, a graduate of the Western Reserve University Medical Department, in 1888, died at his home in Wheeling, W. Va., following a paralytic stroke, on September 13, aged 60 years.

Dr. William F. Barclay died at his home in Pittsburgh, Pa., on September 9, aged 76 years. He was a graduate of Jefferson Medical College, in 1866, and a Civil War veteran.

Dr. Emory Judson Walker of New Haven, Conn., a graduate of Hahnemann Medical College and Hospital, Chicago, in 1868, died on September 11, aged 75 years.

Dr. John B. Sanders, formerly of Mounteville, Ga., a graduate of the Southern Medical College, Atlanta, in 1888, died at LaGrange, Ga., on September 16.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE BRITISH HOSPITALS ASSOCIATION—THE VOLUNTARY HOSPITAL SYSTEM—THE COMMON SURGERY —MEDICAL WORK AT BRADFORD.

LONDON, September 5, 1918.

THE British Hospitals Association has for its main object the facilitation of the means for considering and discussing all matters connected with hospital management; where advisable the association takes measures to further any decision arrived at by its governing council, and in all events promotes opportunities for the acquisition of a knowledge of hospital administration. To this end the hospital arranges for the reading and discussion and publication of approved papers, and holds conferences where all matters relative to hospital construction and management can be threshed out by experts actually engaged in the practical side of the work under deliberation, so that the many difficult points which arise in the granting of medical relief to the poor in charitable institutions, in semi-charitable dispensaries, and under the Poor-Law may be elucidated by a pooling of information and a comparison on sifting of ideas. The council of the association has just circulated a pamphlet dealing in a clear and exhaustive manner with the important question of the future relation of the voluntary hospitals to the impending Ministry of Health. The statement has not yet been formally considered by the council, but it has been printed and circulated under their ægis, having been written by Mr. Courtney Buchanan, secretary and house governor of the Metropolitan Hospital, who is also the secretary of the British Hospital Association. The main message of the pamphlet is to urge that the voluntary hospital system, which is threatened by many of the tentative schemes now being formulated for medical treatment under the impending act, should be permanently maintained. Mr. Buchanan defines the functions of a voluntary hospital as those of a medical, surgical, and nursing school; the institution should supply "treatment by specialists, such treatment being made in every respect as perfect as possible." He postulates that the hospitals in which treatment of this order is given should be equipped and maintained, in all their special and general departments, in the highest state of efficiency and adapted to the requirements of the latest medical, surgical, and nursing science and education. With this ideal ahead, he indicates that the service of the voluntary hospitals should be supplemented where necessary by any service, State or municipal, that comes into being by the creation of a Ministry of Health, and should be directed to three main purposes:—(1) to treat the most grievous forms of disease; (2) to raise the general standard of all medical and nursing education; and (3) to advance and facilitate, with bacteriological and pathological investigation, all scientific research. This last item in a sweeping program is a direct challenge to those people, many of whom are as silly as they are nobly intentioned, who protest that scientific research in a hospital is another word for experimentation upon the suffering bodies of the poor, and who view the association of a medical school with a hospital as a method whereby the student can get his prentice hand in by bungling endeavors to deal with defenseless patients. There are such people, and they have a noisy voice even in the House of Commons, so that it is well that the issues should be put directly before them. Centers of learning such as Mr. Buchanan has in his eye would be open only for the treatment of acute accidents, and for serious cases, selected as suitable by the general practitioners of the district. It should be possible to eliminate trivial cases, and send to the hospital for treatment only those which constitute pathological problems, and as the diagnosis would in the first instance be left in the hands of the general practitioners their energies would be brought into correlation with hospital practice in a way which does not now obtain. The elasticity of organization and flexibility of adaptation which can be obtained in a voluntary institution with much greater certainty than in a State institution, would develop this correlation in a striking manner, while it will be easy to further support this fusion of general therapeutics and scientific research by the establishment, under the new act, of clinics, surgeries, and subsidiary medical centers, grouped around and in touch with the voluntary hospitals. Mr. Buchanan makes out a strong case for maintaining the voluntary hospital system.

The drain upon the personnel of the medical profession by the demands of the navy and army has brought about a revolution in medical service which would not have occurred in two generations of peaceful development. Medical men have been driven to some extent to pool their resources, with the result that the way is already being prepared for the institution of just such local centers as Mr. Buchanan asks for in the pamphlet upon the voluntary hospital system which I have just annotated. A writer in the *Evening Standard*, who is obviously well acquainted with the condition both pre-war and now in existence, has written a forceful article pointing out the waste of medical labor involved in the neglect of the services of the capable nurse. The common surgery, as he styles the therapeutic center at which the general practitioners of a district would make a combination of their efforts, ought, he points out, to be provided above all things with a trained nurse, capable and properly instructed in the conduct of a medical practice. His definition of the duties of such a woman certainly asks a great deal of her, and one weak spot in the idea is that the supply might not be equal to the demand. He writes: "It would be the nurse's business to receive messages, interview callers, and decide what cases were so urgent as to demand immediate attention. A highly qualified woman, possessing tact and initiative, could greatly lessen the burden of the medical man's work, without in the least diminishing its efficiency. Fully half the cases in which a doctor is called in present no difficulty of diagnosis which an educated woman, with clinical experience, could not meet. Many of them could actually be treated, at least in the preliminary stages, by the nurse, and the doctor could be relieved, after full diagnosis, of a great deal of sheer routine attention. Such an arrangement would not merely save time and labor; collaboration would freshen the ideas of the general

practitioner, who is exceedingly apt to get stale, and the fact that a second or third mind would be always available in difficult cases, without special expense, would be a great advantage to the patient." Another weak spot is that a person not a doctor (for "highly qualified" in the above quotation does not mean "holding high medical qualifications") would be apt to be blind to her own limitations. It is true that many cases in general practice could be effectively treated by a capable nurse, if the diagnosis had been accurately made, but the risk of not seeing the serious condition underlying the apparently trifling symptom might be serious. To relieve the hard-worked general practitioner of such part of his routine as demands no basic scientific knowledge would be an admirable thing, but the diagnosis of cases in the first instance must be made by the man having the necessary education and outlook. For this reason the economical idea of having a resident nurse at a medical center, where the joint work of a group of medical practitioners is being carried on, must be received with caution, and I doubt very much if the General Medical Council would sanction such an innovation, however highly qualified the nurse were in her strictly nursing duties. Under the scheme of the writer in the *Evening Standard* the nurse would be doing medical work under the names of her group of employers; these employers would thus be guilty of the professional misdemeanor of "covering" and would be liable to removal from the Medical Register.

Bradford has for many years been in the vanguard of work for children, serving as an example for other municipalities, and Councillor E. J. Smith, the chairman of the Health Committee of the Bradford Corporation, has written a useful volume entitled "Race Regeneration" out of the fullness of his experience. Mr. Smith has been long a voluntary worker in Bradford's schemes, and his book is perfectly equipped with the technical detail and overflowing with useful suggestions for the future development of similar civic work. The book contains a chapter on a Ministry of Health and a detailed description, with illustrations, of the Bradford Maternity and Child Welfare Scheme and the Bradford Post-war Housing Scheme. It must not, however, be supposed that the book has merely a local interest, for such national questions as the endowment of motherhood, the race suicide brought about by venereal disease, the poverty of our educational system, and the effect of industrial conditions upon the great mass of the people are ably and sympathetically discussed. Messrs. P. S. King & Son are issuing early in September a shilling pamphlet on Housing, also from the pen of Mr. Smith, which sets out, *inter alia*, the Bradford plans for post-war housing of its workers in ten model villages of the garden-suburb type. Students of housing should critically examine these proposals. They present several new features in keeping with new ideals of race regeneration, recognizing as an indispensable factor the improvement of the environment into which the children of our workers are born. Shortage of living room presses heavily on large towns, but the cottage famine in rural districts is equally notorious. Since, as Mr. Smith points out, the future is largely dependent upon the "security of unborn children," the ways and means by which this security may be conserved and consolidated must be seriously considered.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

INCREASING THE HOSPITAL ACCOMMODATIONS—SHIFTING CANTEEN NEEDS—THE HUN'S REVENGE, BOMBING A HOSPITAL—JUNE REPORT OF THE AMERICAN RED CROSS—Y. M. C. A. HEROES—ITALY HONORS AMERICANS—A HEROINE DECORATED—PAPWORTH HALL COLONY FOR THE TUBERCULOUS.

PARIS, August 20, 1918.

THE number of beds in American Red Cross Hospital No. 5, near Paris, has been increased from 500 to 1,000, and it is now regarded by all authorities as our model hospital. Doctors hold it up as a standard. Plans are under way greatly to increase five of our hospitals. The Red Cross Hospital at B—— handled more than 1,300 cases in June. We are negotiating for two most important hospital undertakings, one as a special hospital for skin diseases and the other as an Allied hospital for gas cases. One hospital, serving as an evacuation hospital for American troops in the French sector, did more than 100 operations in twenty-four hours. Another hospital for the navy is filled and its capacity is being increased. Still another hospital for the navy is planned. We have established a dispensary and a medical and dental office for the auxiliary personnel and are opening dispensaries at Bordeaux, Lorient, and Nantes. There are three convalescent homes serving officers and enlisted men, and another is about ready for aviators. A fifth convalescent home is to be opened this month. The nursing service has furnished thirty-seven teams of French-speaking American Red Cross nurses to French hospitals with American wounded. They assist in the care of the American patients and act as interpreters between the American wounded and the French staff.

The line of communication service section has opened new canteens at three points and reopened two which had been temporarily discontinued. Canteen needs shift rapidly in some cases. One canteen serving 2,000 meals early in June dropped to 300 meals a day, while another, after closing for lack of work, reopened and served 7,000 meals the first five days. The canteen garden at an aviation center is much appreciated by the soldiers. At Limoges the dormitories are crowded every night, and 500 men are served daily. The requisition and equipment section between June 8 and 29 received 1,412 requisitions. We have carried out requisitions with goods from Paris warehouses valued at more than $517,000, in addition to shipments from points outside Paris. The home and hospital communication section received 4,435 letters and was able to give the information requested in 2,980 cases. In the field service section our canteen service at the front with the French troops now operates thirty posts, with seventeen representatives. A new office of corps representatives and a new system of storage and

supplies greatly facilitate our work with the American troops in the field. Newspaper and magazine contributions to American Army divisions are increasing. Thirty thousand magazines were distributed to more than 150 units in June and 600,000 newspapjers, an increase over May of 7,000 magazines and 200,000 newspapers. We are developing the system to supply all men in hospitals or on active service with reading material.

The American Red Cross Military Hospital No. 1, in Neuilly, has again been able to increase its number of beds in preparation for receiving the wounded from the present big battle. Owing to the fact that the entire upper floor has been released by the men who formed the Paris sections of the United States Army Ambulance Service and who were housed there until they were transferred to the Longchamp racecourse, new wards are being installed.

Mr. C. S. Wheeler, representative of the Red Cross Hospital at Jouy, reported to Paris headquarters yesterday morning that German aviators deliberately bombed the hospital at that point at 11 o'clock on Monday night. Two enlisted men among the personnel were killed and nine persons injured. Doctors were operating on four tables at this time and the hospital was full of wounded. The operations continued throughout the raid, during which at least three bombs dropped. One of them destroyed three tents. Additional teams of doctors were telephoned for immediately and the work at the hospital continued without interruption. Whenever the Hun loses a battle or suffers a reversal he takes it out by bombing a hospital, sinking a hospital ship, or making an air raid on Paris.

Following a careful investigation by a Red Cross officer a more extensive report of the bombing at Jouy was presented to Colonel Harvey D. Gibson, Red Cross Commissioner for France. Four bombs were dropped on the hospital at 11 o'clock, at least two German machines participating in the raid. Two bombs fell fairly on the roofs of hospital tents, one fell 7 feet from the wall of another tent, and one failed to explode. The bombs made only a hollow depression in the ground and were evidently designed not for penetrative power, but to scatter their fragments over as wide an area as possible. There are no structures of any kind near the hospital, and the railway tracks are nearly two miles away. In addition to the usual markings of a hospital, on the lawn immediately adjoining is a cross formed of white duck, the extreme dimensions of the arms of the cross being 30 yards. Photographs recently taken from an aeroplane show that this cross is visible several thousand feet in the air. All question as to the deliberate character of the raid is removed by the corroborative statements of seven witnesses, who state that the Boche aviators flew back and forth several times, then shut off their engines, came down to within a few hundred feet and dropped their missiles after careful observation that could not have failed on a bright, clear night to show that they were bombing a hospital.

Of the enlisted men killed one was fatally injured in the stomach as he stood 40 feet from the window of the operating room, which was pierced by two pieces of bomb. These fragments passed within 4 feet of Major J. C. McCoy, the surgeon-in-charge. Major McCoy was holding the exposed femoral artery of a patient when the bombs fell and all lights went out, leaving his own and two other operating tables in darkness. The other orderly killed was holding up a patient to give him a drink, when the orderly's chest was torn open by a bomb fragment. One of the nine hospital attendants injured had his leg amputated on Tuesday. One of the four patients rewounded received a piece of shell in the identical wound in his back from which a piece of shrapnel had been removed a few hours previously. He is Private Joseph A. Siline of Philadelphia, and will recover from both wounds. Miss Jane Jeffery, the only Red Cross nurse who was wounded, was struck near the spine by a piece of metal which traversed the entire length of a ward only a few inches above a long row of surgical and gas cases, and penetrated the end wall of a tent outside of which she was standing. Miss Jeffery, whose home address is Dorchester, Mass., is not seriously hurt and will recover, according to the statement of Major McCoy.

C. S. Wheeler, who has worked indefatigably on the installation of the Jouy hospital, was on the ground at the time of the raid and directed his first efforts toward getting the personnel out of danger. He left early in the morning for Paris for additional supplies, which were delivered at the hospital before 4 o'clock Tuesday afternoon. The wrecked interiors of the two wards hit have been carefully photographed. The Jouy Hospital had until recently sixty German wounded prisoners who received exactly the same treatment accorded other patients and were given the special delicacies provided for the Fourth of July. All were most grateful, except one German lieutenant among the prisoners, who violently objected to being cared for in the same ward as his men.

The June report of the activities of the Civil Affairs Department of the American Red Cross gives a further increase in the amount of work accomplished. Seventeen delegates gave special war zone relief in eleven departments and ninety-two delegates and associates aided refugees in seventy departments throughout France. Under medical direction three refugee homes are housing 1,500 children from the war zone. In Paris 32,000 school children are getting supplementary food for luncheons at the schools. Seventeen civilian hospitals are in good running order, with a total capacity of 1,698 beds, including the new hospital for mutilés opened during the month. Sixty-one dispensaries for children or tuberculous refugees care for 45,028 patients. Two electrical workshops and recreation halls have been completed for the French school for the reeducation of war cripples.

The emergency refugee relief committee aided 45,000 refugiés passing through Paris during the period from May 27 to June 30. The total number of civilians aided during the month was 412,563, of whom 127,043 received aid from the Children's

Bureau; 10,179 tuberculous, 10,168 mutilés, 38,638 from the War Zone Bureau, 226,638 refugees or refugee children, showing an increase of 85,353 civilians aided over previous months. The supplies distributed by all the bureaux included 296,710 garments, 56,647 pairs of shoes, 17,222 articles of furniture, 60,078 articles of bedding and household linen, 85,570 yards of cloth, 668,672 pounds of food, 4,287 articles of hospital equipment and supply. The money grants to outside organizations totaled 921,585 francs of which 435,477 francs went to the tuberculous, 345,353 francs to refugees, 38,000 francs to relief in war zone, 70,505 francs to children, and 32,250 francs to mutilés.

Y. M. C. A. men have performed heroic deeds during the new German push. Henry J. Johnston, East Orange, N. J., who was cut off by the German barrage for six hours, finally broke through with a small squad of Americans and worked all day helping to bring in the wounded and assisting the doctors in the advanced dressing stations. G. A. Crispin, Charleston, Ill., and the Rev. F. A. Cunningham, Providence, R. I., served as stretcher-bearers, and cared for the wounded in dugouts until they were ordered by the commanding officer to move back. All the Y. M. C. A. supplies in the attacked zone were given free to the soldiers, some of whom had lost their rations. W. H. Danforth of St. Louis, Mo., Richard Shreve of Rochester, N. Y., and others stuck to posts in the advanced areas, distributing supplies, helping ambulance men, and making wounded more comfortable. Mack Strong of Selma, Ala., and William J. Symons of Whittier, Cal., were under shell fire for nine hours in the cellar of a Y. M. C. A. canteen. Men were killed and wounded all about them, one being killed in a room overhead. After the barrage lifted they remained at their posts distributing supplies gratis to the wounded. Dr. William Doidge of Passaic, N. J., and William P. Gwin of Gadsden, Ala., rendered aid to the wounded under fire. Dr. Doidge took twelve wounded back to the dressing station.

The twenty-one members of Section 3 of the American Red Cross ambulance service in Italy have all been awarded the Italian War Cross for conspicuous gallantry in serving Italian troops during the recent offensive. These Americans were under a continuous fire day and night, performing work of the greatest importance. The members of Section 3 who received the War Cross are Lieut. E. Paskum, the chief of the section; J. H. Tedford, James Eaton, Harry F. Gibbe, Raymond T. Hanks, Wisted G. Henderson, Wilard H. Hohl, Charles H. Masters, George C. Moyes, Malcolm G. Olson, Grant M. Palmer, Bryant Prescott, Robert Rieser, Winthrop Slade, Jr., Henry N. Spellman, Amory Thorndike, Edward T. Dougherty, George S. Piper. Other ambulance drivers have also been mentioned for special distinction but their names have not yet been made public.

M. Clémenceau, Minister of War, has on the proposal of the Commander-in-Chief, awarded the Cross of the Legion of Honor and the Croix de Guerre to Miss Fraser, a British automobilist attached to a sanitary section, who was severely wounded in the exercise of her mission. She is mentioned as follows: "Charged on the night of July 18 to 19, 1918, with the transport of wounded, she accomplished her mission under a violent bombardment. Having received two serious wounds on the way, her automobile being destroyed by the explosion of a torpedo, she had the superb courage to walk the 200 metres which separated her from a neighboring hospital in order to inform the doctor on service that she was bringing him some wounded. Falling helpless and being transported herself to the hospital for operation, she asked insistently not to be treated until after the wounded for whom she was responsible."

It is felt that tuberculosis among soldiers will be one of the greatest post-war problems in the United States, as it has become already in Great Britain, France and Italy. In this country soldiers suffering from tuberculosis are now being discharged from the army in considerable numbers. Some of the steps which are being taken in connection with the treatment and care of these men are outlined in a report by the American Red Cross dealing with the work of the "Papworth Hall Colony for Tuberculous Soldiers" at Cambridge, England. "An interesting and important experiment," says the report, "in treatment of tuberculous soldiers has been inaugurated by the British authorities at Papworth Hall. Here an estate of 100 acres of park and woodland has been turned into an open air sanatorium, where the patients will undergo treatment and at the same time work at suitable trades. It is generally admitted that no country can afford to neglect immediate and adequate attention to the problem of soldiers discharged from the army owing to tuberculosis. Unless great care is taken, these men will prove centers of infection, not only in the workshop but also in the street, in public conveyances, and in the home. The chief medical adviser of the Papworth Hall Colony estimates that the working capacity of the average consumptive soldier, after he has been discharged as convalescent from the military hospitals is less than 50 per cent. of that of the healthy workingman. The principle of the Papworth Hall experiment is the subsidizing of tuberculous labor. It aims to supply the other 50 per cent. of the man's earning capacity. The ex-soldiers already assigned to the Papworth Hall Colony are at work as carpenters, tailors, and market gardeners."

Sir George Fordham, head of the Papworth Hall work, in a letter to the American Red Cross says that "The myth which has so long held sway that a tuberculous man must give up indoor employment and find an outdoor situation must be dispelled. It is absurd to imagine that the average city clerk will consent to remove himself and his family to the country and turn himself into a laborer. Many of our failures in the past have been due to the idea that every patient must have fresh air even at the cost of a bare larder. We are now beginning to realize that diet is of the utmost importance, and although fresh air runs a good second, all the fresh air in the world will not fill an empty stomach."

1. Fatigue and Exhaustion. Remarks on Phenomena and Energy Renewals.—J. Madison Taylor points out the importance to the worker of the mental attitude towards labor. This fact deserves wider recognition in the industrial world, the one practical method of obtaining industrial contentment and efficiency being the study and betterment of working conditions by capitalists with a view to maintaining the welfare and cheerfulness of workers. The crux of production is the question of fatigue, which may be described as the evidence of result of strained attention, the presence of waste products interfering with the normal action of the cells and leading to impaired interaction and equilibration. Since fatigue feelings, as a rule, begin long before the structures are materially affected, appeals to the emotions, to loyalty or ambition, will result in renewed effort. Thus, a word of praise or encouragement, music, a brief change from action to rest, or of position, will reinvigorate. The value of all forms of recreation cannot be overestimated; play is next in importance to rest. Mental influences are both excitatory and inhibitory; enthusiasm will carry one beyond ordinary endurance, whereas distressing news or an unkind word will interrupt energy and lead to motor and other functional confusions, weariness, and disease. Madison Taylor points out the value of exercise and the importance of keeping in condition. He shows the folly, however, of unaccustomed violent exercise which makes a severe call on long disused muscles, which use up oxygen and produce CO_2 faster than the heart and lungs can supply the one and remove the other. In middle-aged, out-of-condition or sedentary people the effect of air hunger should not be ignored, particularly after an illness, in any infection, or after severe strain especially when accompanied by a cold or tonsillitis. Another peril is "fatigue anesthesia," when from long disregard of fatigue phenomena the governor is removed from the human machine and it may readily come to grief. Brain workers do not consume so much fuel as muscle workers and, therefore, accumulate less body poisons. Cerebral tissues readjust themselves more readily. But the brain worker is seldom free from exhausting muscle work, such as protracted tension from cramped postures. Especially are the eyes overworked and congested. Gardening, carpentering, the use of tools, or the punching bag bring about the needed relaxation of mental overtension. In short, system and discretion are needed both in work and play, and no higher physical happiness is attainable than that obtained by a commingling of well-earned weariness and judicious energy renewals.

1. The General Diagnostic Study by the Internist.—Lewellys F. Barker. (See MEDICAL RECORD, February 9, 1918, p. 259.)

5. Appendicitis in Children.—John O. Bower points out that clean cases of appendicitis (those in which it is not necessary to insert a drain) are unusual. In reviewing the case records at the Samaritan Hospital two years ago, he found that at least 90 per cent. of patients under fifteen had peritonitis, either local or general, and that the mortality was four times greater than in a corresponding number of adult cases. In Deaver's series 85 per cent. had abscess formation and the mortality was 4.6 per cent. These facts demonstrate the importance of early diagnosis of the condition in children. In considering the etiology, predisposing factors play an important rôle: appendicitis is frequently associated with influenza, measles, acute rheumatism, enterocolitis, typhoid, and tonsillitis (which may be due to an excess of lymphoid tissue with thinning of the submucous coat); abdominal injury predisposes to appendiceal inflammation in the young adult, 2.5 per cent. of cases giving such a history; fecal concretions are usually larger and are more frequently found in early life; intestinal parasites, though uncommon, are more frequently associated with appendicitis in juveniles; foreign bodies are more often found in appendices in children than in adults. The direct causative factors are the *Bacillus coli*, staphylococcus, streptococcus, *Bacillus pyocyaneus*, and the tubercle bacillus, in order of frequency as named. Tuberculosis of the appendix, which in adults is secondary to a pulmonary lesion, in young adults usually follows or accompanies a general abdominal tuberculosis. The symptoms are the same as in adults—pain, which is variable in children and is usually abdominal at first and, later, localized in the right lower quadrant; nausea and vomiting, which in the majority of cases follow the pain and are also more variable in children, the severity depending on the causative germ. In streptococcus infection, the most severe vomiting occurs; it is less in staphylococcic, and least in colon and tubercle infections. Localized tenderness before the involvement of the parietal peritoneum is not constant. Since the appendix in children varies in position, there is little abdominal rigidity in some cases; however, when the parietal peritoneum becomes involved the abdomen becomes rigid and distended. Temperature is variable and in most cases of moderate degree; in streptococcus infections there is the highest temperature, a sudden drop indicating perforation or gangrene. Bower calls attention to the fact that in tubercular involvement of the cecum and appendix there may be only an afternoon rise to 99.3°, or an entire absence of temperature for several days. A blood examination is valuable in doubtful cases: a leucocytosis may be obtained before involvement of the peritoneum or appearance of temperature. Urinary frequency is often present. These symptoms, especially with a leucocyte count of 15,000 within the first eighteen hours, point to appendicitis, and if pneumonia can be excluded the diagnosis is certain. The importance of a rectal examination should not be forgotten. If in very young children the possibility of a chest condition has been eliminated, ether or chloroform may be administered to overcome the spasm of the recti. *Differential diagnosis:* Ptomaine poisoning or acute gastrointestinal colic is the usual diagnosis in a large percentage of cases that come to operation; in such cases, the presence of diarrhea, absence of leucocytosis, cessation of vomiting following stomach lavage, and history of some indiscretion in diet, make the diagnosis of toxemia evident. Acute pyelitis is often associated with abdominal pain; the dominant symptom is usually fever and correct diagnosis may be reached by the microscopic examination of a centrifugal specimen of urine. A possible vaginitis should be excluded. Intussusception in children may be ushered in by a sudden cry. A sausage shaped mass that varies in position, the presence of characteristic vomiting of overflow intestinal obstruction, with blood-stained mucous stool, absence of rigidity, leucocytosis and temperature are diagnostic features in this condition. In pneumonia, points to be remembered are the respiration, pulse ratio, and intermittent spasticity of the recti, herpes and high leucocyte count. In acute perforation of the stomach, the pain is most severe; there is marked abdominal rigidity and patients vomit immediately the drug or laxative given by mouth; in early cases temperature is usually subnormal and pulse comparatively slow. In acute pancreatitis, a history of preceding attacks of colic points to a diagnosis of pancreatic inflammation. Abdominal tuberculosis of one type or another is found in 90 per cent. of cases of appendicits in children preceded by attacks of similar nature.

There is an apparently normal appendix, which together with the rest of the contents of the abdominal cavity may appear anemic, a variable amount of free fluid, and frequently the enlarged mesenteric glands in the neighborhood of the cecum or bowel, or the bowel itself, are studded with numerous tubercles. In such cases universal improvement follows appendectomy (the proper treatment in early tuberculosis of the abdomen being an exploratory laparotomy). *Treatment:* Immediate operation is indicated in practically all types of appendiceal inflammation, the exceptions being: (1) Early perforations with widespread peritonitis due to the streptococcus; (2) Cases of general peritonitis of several days' duration. The Ochsner treatment has been found to give excellent results in such cases, but it is a difficult procedure in children. At the Samaritan Hospital the author has found that these cases do better if drainage is instituted. Local or intraspinal anesthesia may be used. The latter gives the following advantages: the pateint's emunctories are not interfered with; relaxation of abdominal muscles permits insertion of a drain with the least possible amount of manipulation of abdominal contents; paralysis of the bowel and sphincter permits evacuation of contents of the lower bowel.

A Study of the Diet of Nonpellagrous and of Pellagrous Households in Textile Mill Communities in South Carolina in 1916.—Joseph Goldberger, G. A. Wheeler, and Edgar Sydenstricker undertook in the spring of 1916 a study of the relation of various factors to pellagra prevalence in cotton mill village communities in South Carolina. This investigation was begun to supplement experimental studies made under the direction of Goldberger in 1914 and 1915, which had demonstrated the controlling influence of diet in both prevention and causation of this disease. In 1916 pellagra incidence was determined by a systematic bi-weekly house-to-house search for cases, carried on from April 15 to December 31 of that year. The diagnosis of pellagra was restricted to cases presenting a definite, bilaterally symmetrical eruption, which, it is suggested, includes two commonly associated, etiologically distinct, though closely related syndromes. Data relating to household diet were secured by obtaining records of sale from the principal stores for fifteen days immediately before or coincident with the incidence of the attack as suggested by the seasonal curve, supplemented by inquiries of a trained investigator. Comparisons of diets of nonpellagrous with those of pellagrous households showed that: (1) The nonpellagrous enjoyed a larger supply of the animal protein foods; (2) Varying supplies of fresh meat were associated with a corresponding (inverse) variation in the incidence of pellagra; (3) Varying supplies of milk were associated with a corresponding (inverse) variation in the incidence of pellagra; (4) The calorific value of the diets of pellagrous households was somewhat less than that of nonpellagrous households, but this, nevertheless, conformed to recognized standards and could, therefore, not be considered as an *essential* factor in relation to the incidence of pellagra; (5) The total protein supply in the diets of pellagrous households was somewhat less than in nonpellagrous households, but was not below Chittenden's standard and, therefore, a deficiency in total protein would seem not to be an *essential* factor in relation to the incidence of pellagra; (6) The proportion of protein from animal food tended to be somewhat smaller and that from cereals, peas, and beans, somewhat larger in pellagrous than in nonpellagrous households, and therefore the protein in the diet of the nonpellagrous was likely to be of better quality; (7) In pellagrous households the diet included somewhat less carbohydrates, and therefore the production of pellagra is not necessarily dependent on an excessive consumption of carbohydrates; (8) There was decidedly less fat-soluble and also water-soluble vitamin in the diets of pellagrous households; (9) The mineral constituents of the diets of the nonpellagrous households was likely to be superior—less likely to be defective. From these findings the authors suggest that the pellagra producing dietary fault is the result of some one, or more probably, a combination of two or more of the following factors: (1) A physiologically defective protein supply, (2) a low or inadequate supply of fat-soluble vitamin, (3) a low or inadequate supply of water-soluble vitamin, and (4) a defective mineral supply. They refer to the fact that McCollum, Simmonds and Parsons, from their studies in rats, concluded pellagra is primarily associated with the unsatisfactory character of three dietary factors, namely, a shortage of the fat-soluble "A," the faulty character of the inorganic moiety, and the relatively poor quality of the protein mixture. They also suggest that the somewhat lower plane of supply, both of energy and of protein, of the pellagrous households, though apparently not an essential factor, may be contributory by favoring the occurrence of a deficiency in intake of some one or more of the essential dietary factors, particularly with diets having only a narrow margin of safety, and that the pellagra producing dietary fault may be corrected and the disease prevented by including in the diet an adequate supply of the animal protein foods (milk, butter and lean meat).

1. Thoughts on the Employment of Pregnant Women in Munition Factories.—Mary A. S. Deacon. (See MEDICAL RECORD, September 28, p. 559.)

7. Influenza and Purulent Bronchitis.—Captain A. Maude describes the epidemic outbreak of influenza that occurred in England in June, 1918. Uncomplicated cases were characterized by short incubation and sudden onset. Patients complained of giddiness and generalized pain; conjunctivitis was frequent, infection of throat and tonsils rare, and gastric symptoms present only in subjects of previous gastric affection. In two commands of combined strength of 10,000, there were 2,067 cases between June 18 and July 18, 248 being admitted to hospital. A high proportion of these developed purulent bronchitis, as described by Hammond in his cases at Aldershot. A large number also showed a frank lobar pneumonia, usually of the lower lobes only, but in three instances consolidation was apical. These three cases were severe and accompanied

by acute, brief delirium. Physical signs developed slowly and had little relation to the temperature. The commonest type was a pneumonia of limited extent, accompanied and often preceded by coarse bronchial signs. Pneumonic patches were bilateral with tendency to spread. The combination of coarse bronchitis and lobar pneumonia produced grave dyspnea and profound effects on the heart, especially on its right side. Physical signs of bronchitis were frequently combined with patchy signs of consolidation. In many cases the signs of bronchitis supervened upon those of localized pneumonia and the bronchitis was frequently one-sided, showing its infective quality. Small patches of collapsed lung were a frequent sequel to the bronchitis; the collapse was of short duration and completely cleared up. The sputum rarely showed the "prune-juice" staining of ordinary pneumonia, though sometimes tinged with bright blood. It was usually a faint crushed strawberry. Expectoration became tenacious, yellow, and consisted of almost pure pus, often in tough curdled casts, evidently from middle-sized bronchi; there was no offensive odor. Although no systematic bacteriological examination was undertaken, the question of double successive infection by the influenza bacillus and the pneumococcus was established. Pleuritic patches were frequent, especially in the right base, the pleurisy often heralding the lung attack. The "heliotrope" complexion, noted in the Aldershot series, was present in many of the worst cases, but these were not uniformly fatal. Few of the lobar pneumonia cases terminated by crisis, and lysis was often irregular; temperature sometimes reached 105° or 106°, but in only one instance was there a typically pneumonic chart. A fall in temperature was frequently followed by renewed pyrexia and with purulent expectoration the temperature was of swinging type with a range of several degrees. The severer cases were characterized by rapid emaciation. Of the men admitted to hospital three died, all from extensive double pneumonia. Several of those most seriously affected were subject to bronchitis. Treatment by expectorants, combined with free alcoholic stimulation and heart tonics, was found to be of most avail. Pulmonary antiseptics and inhalations proved useless, oxygen was of no value, and atropine seemed to interfere with pulmonary secretion and to do more harm than good.

1. Observations on the Etiology and Treatment of Seborrheic Eruptions. A Preliminary Report.—Captains H. W. Barber and H. C. Semon noted in a large number of their cases of seborrheic eruption an associated nasal and nasopharyngeal catarrh, which with the frequency of relapses led to the conception of an underlying constitutional dyscrasia as a possible cause of the disease. Darier has pointed out the relation between seborrheic eruptions and "kerose" skin and has indicated the etiological factors as being sexual development and erroneous diet, in which excessive carbohydrates and stimulants, faulty mastication, and constipation all played a part. The present authors share Darier's view that the bacteria described as specific by Sabouraud and Unna owe their activity and pathological effects mainly to the soil on which they grow, which in its turn is dependent on the underlying constitutional state of the patient—a view which furnishes an explanation of the frequent relapses suffered. In view of the frequent association of nasal and nasopharyngeal catarrh with the outbreak on the skin, an examination of a number of cases was made by Captain C. Jones-Phillipson, who found that in 59 out of 93 cases posterior rhinoscopy revealed a yellowish mucopurulent secretion, of varying amount. Simultaneously a streptococcus of the *faecalis* group (in addition to numerous staphylocci) was recovered from nasal mucosa and skin eruptions. Czerny has shown that certain children present a congenital susceptibility to catarrh as well as to certain nervous disturbances, and to this tendency he has given the name "exudative diathesis," the extreme form of which is known as the status lymphaticus, when secondary changes in the lymphoid tissues of the body have given rise to adenoid vegetations, parenchymatous tonsillitis and adenitis, especially localized in the cervical glands. The manifestations of this diathesis are provoked by excess of diet, and its subjects are particularly intolerant of carbohydrates and fats. In England Czerny's views have been strongly supported by H. C. Cameron, who has pointed out that children of the exudative diathesis, or status catarrhalis, are subject to an extreme "wateriness" of their tissues which gives them a fictitious appearance of plumpness. Barber and Semon indicate two types of seborrheic individuals, those congenitally predisposed, or who have acquired the tendency in infancy, and those in whom the state has suddenly appeared as the result of active service. Patients in the first group are far more prone to relapse than those of the second type, and prognosis is more favorable in the latter. As a result of their investigations these authors conclude: 1. That there is a constitutional state which may exist from infancy or may appear *de novo* in adults, and which may be termed the status catarrhalis or exudativa (Czerny). Where this condition exists the skin and mucous membranes show an abnormal susceptibility, not only to various bacterial infections, but also to mechanical and chemical irritation. 2. Persons in whom the status catarrhalis is present, either permanently or temporarily, are liable to develop the multitudinous eruptions which have been variously termed seborrheic eczema or dermatitis, true eczema, pustules, boils, and the wrongly termed "impetigo"—really an impetiginized seborrheic eczema. These manifestations, in whole or part, are intimately dependent or associated with the existence of an underlying dyscrasia, to which they have given the name of the status seborrheicus. 3. There is considerable clinical and therapeutic evidence to suggest that all patients with the status seborrheicus are suffering from a relative acidosis. We are of opinion that this condition may have resulted from a diminution of the intake in their food of the fixed bases—the mono- and di-sodium phosphates, and the carbonates, which are normally present in fresh fruits and vegetables, and which are largely responsible for the maintenance of an exact alkaline-acid equilibrium in the blood and tissue fluids. 4. As a practical outcome of these considerations there is abundant clinical evidence of the value of alkalis in the treatment of seborrheic eczema.

Berliner klinische Wochenschrift.

July 22, 1918.

Cystic Colitis and Its Relation to Dysentery.—J. Orth, basing his discussion of this question on the histologic description of the various types of cystic formation met with in the intestinal walls, concludes that one may define several distinct nosological types: (*a*) small retention mucous cysts, arising from transformation of the glands; (*b*) retention cysts, resulting or not from glandular débris comprised in the lymphoid masses; (*c*) larger submucous cysts. The corresponding clinical pictures are: superficial cystic colitis, belonging to the first class of cysts. The others are inflammatory processes belonging rather more especially to dysenteric processes (deep-seated cystic colitis). These various pathological types are illustrated by some microphotographs. The writer offers a study of mucoid grains met with in dysenteric stools. They are formed either in the cystic cavities by concentration of the mucous content or by mucous secretion on the surface of nuclei composed of residual products of digestion, etc.

Operative Stricture of the Nasal Cavities.—Schönstadt proposes as a treatment for various nasal affections, particularly ozena, a submucous bone graft on the nasal floor. The graft is taken from the patient's tibia and measures 2.5 by 3 centimeters. The route of attack passes through the superior maxillary at the level of the gingivo-labial fold. After making his incision, Schönstadt slowly peels off the mucosa of the nasal floor and introduces the bone graft on the right and left of the septum. Suture of the incision. The integrity of the nasal mucosa is necessary in order to obtain fixation of the graft.

Münchener medizinische Wochenschrift.

July 16, 1918.

The Blood Serum Content of Cholesterin in Disease.—W. Stepp says that cholesterin is supposed to pass from the intestine into the circulation, becoming accumulated in the liver, suprarenals, etc., and is afterward eliminated by the biliary tract and intestine. Cholesterinemia of normal subjects remains at quite a fixed point. Stepp has been able to verify Chauffard's, Griguant's and others' researches and finds that it varies from 0.13 to 0.17 per cent. In diabetes, the writer shows that there is an approximate parallelism between the glycemia and the cholesterinemia present. The famous "diabetic lipemia" is, in reality, much more a "lipoidemia." The writer recalls the rarity of the acidoses and diabetic coma since the war has imposed certain food restrictions, particularly that of fat. Hepatic diseases are frequently accompanied by cholesterinemia of an exaggerated type, preferably in retention icterus (cholesterinemia by retention). Although the rule is not constant, Stepp believes that the phenomenon is to be attributed to the digestive disturbances accompanying biliary obstruction. In lithiasis the cholesterin blood content has been confirmed by Stepp's researches. In a case of Weil's disease a prolonged and accentuated hypercholesterinemia was present. In the nephritides and febrile affections, Stepp's researches confirm the data generally admitted at present. This is likewise true of pregnancy.

The Repair of Large Loss of Soft Tissue by a "Muff" Plastic Operation.—Bode reports two cases of extensive tearing off of the integuments of the hand and elbow. When such lesions are left to undergo an aseptic spontaneous evolution, they result in deformity and contractures which are little better for the patient than if the limb had been amputated in the first place. Bode has been able to obtain an almost perfect functional result by covering the denuded parts by flaps with a double pedicle made on the chest or abdominal wall. For example, in order to replace the skin of the hand, two vertical incisions are made in the umbilical region on the side of the injured member. The flap forms a bridge, under which the hand is passed as if in a muff. The outer border of the skin flap is sutured to the dorsal aspect of the hand, while the inner one is slit in flaps to cover the fingers. The arm is held in place by a roller bandage and thoroughly immobilized. Later on, when the graft is cut away at its pedicles, the ununited border is in its turn sutured to the wound on the hand. Bode recommends the use of this procedure for the repair of loss of tissue covering joints, fingers, wrist, etc. (This is a method well known to American surgeons at least; an excellent description, with illustrations, is to be found in Murphy's Clinics, Vol. IV, No. 1, Feb., 1915.)

Operative Detachment of Pleural Adhesions, in Order to Produce an Artificial Pneumothorax.—R. Eden reports a case whose evolution is far from brilliant, but nevertheless he recommends this intervention. The thickness and resistance of these adhesions may necessitate their separation from both the costal and pulmonary pleura. The complications to be feared are perforation of cavities and pleural infection to which their contents may give rise. This procedure may be combined with operations on the thoracic wall, such as thoracoplasty, etc.

Wiener medizinische Wochenschrift.

July 20, 1918.

The Pathogenesis of the Nephritides.—G. Singer refers to several points of this question which are already well known, such as the frequency of a disease of the tonsils in the patient's antecedents, respiratory changes during the preuremic phase and the aseptic nature of brightic pericarditis. The happy effect of blood-letting is not due to the hypotensive action of the removal of blood because experience shows that the blood pressure rapidly returns to its former degree. Singer is more inclined to invoke a reflex action which brings about a better circulation in the kidneys.

A Case of Ileus by Torsion.—T. Bal records a case in which an ileus formed above a point in the bladder which had been perforated by a catheter and the latter had been broken off at the point of perforation. This broken bit of catheter pressed upon the small intestine and caused the ileus.

La Presse Médicale.

June 6, 1918.

Dyspepsias of War.—Mouriquand and Bouchut report 200 cases of these troubles seen in soldiers in the rear. They seem to be on the increase. When they mend the subjects are returned to the ranks, perhaps to come back again. All of these subjects are studied with radioscopy and many have their stomach contents analysed, stools and blood examined, etc. Organic dyspepsias are not included in these cases. In other words this not only eliminates ulcer and cancer but stomach disorders which are secondary to gallstone disease, cirrhosis of the liver, appendicitis, etc. The symptoms are somewhat monotonous. Most of the men complain of heaviness, bloating, eructations, drowsiness, hot flashes. Less common are headache, vertigo, precordial anxiety and lassitude. The appetite is diminished or absent, the tongue saburral and there is habitual constipation. Cases exhibiting the above syndrome are classed as flatulent dyspepsia. Less common than this flatulent type is the painful type. Pain develops at a variable interval after food. In a third type vomiting is a leading symptom. In 150 of the 200 patients examined with the screen the stomach appeared to be normal, in 45 there was atonia, while five showed hypertonicity. Of the 150 subjects with normal stomach 110 showed flatulence; while 23 cases of the painful type occurred in atonic stomachs. In the great majority of cases examined stomach chemistry was shown to be normal. In other words subjects of flatulent dyspepsia are neither atonics nor hyperchlorhydrics. Yet for the most part they reached the authors with the diagnosis of dilated stomach. As a rule these patients showed more or less general participation. Emaciation was common as was pallor—in fact they looked as a class like sick men. They were in the prime of youth but had never been robust; for the most part poor folk from the rural districts. Their stomachs had clearly never bothered them before they became soldiers. The authors are inclined to see in these dyspepsias a reflex from nervous and mental overstrain. It is singular that the town dweller, better adjusted to his mental environment, does not develop these dyspepsias. In fact the improved physical conditions and regular habits build him up. The peasant has lived an out of door life with early hours of rest and cannot gain in these respects from army life. Before the war he seemed without nerves and emotional life but quickly develops them. Sooner or later they pass through one or another crisis —shell shock, wounds or an illness of some sort—and the end result is a dyspepsia—ostensibly. But as we have seen the stomach is usually normal in all respects so that these troubles must be classed as psychogenic. Nevertheless in certain cases—as in those men who went through definite periods of convalescence—there was abuse of food. With recovery of appetite the men overate. In regard to treatment suggestion should enter into it. Special centers for these patients not only enable the physicians to carry out an approved regimen for the general ill health (anemia, etc.) but also provide an opportunity for indirect suggestions of great value.

Book Reviews.

COLLECTED PAPERS OF THE MAYO CLINIC, ROCHESTER, MINNESOTA. Edited by Mrs. M. H. MELLISH. Volume IX, 1917. Octavo of 866 pages, with 331 illustrations. Price, $6.50 net. Philadelphia and London: W. B. Saunders Company, 1918.

CONTRARY to custom, there is no prefatory note in this volume, so we are not told whether this includes all papers published by workers in the Mayo Clinic and on the Mayo Foundation during the year 1917 or not. There are thirty-five contributors, some of whom are attached to the Mayo Clinic alone, some to the Mayo Foundation in the Graduate School of the University of Minnesota alone, and some, the majority, are attached to both. The same general arrangement of material as heretofore has been followed. Thus, we find all articles grouped under nine headings. These, with the number of articles in each group, are as follows: Alimentary Canal, 17 articles; Urogenital Organs, 16; Ductless Glands, 7; Heart, 3; Blood, 9; Skin and Venereal Diseases, 6; Head, Trunk, and Extremities, 13; Technic, 2, and General, 10, making a total of 83.

There is an unusually large number of articles; so many, in fact, that it is hard to single out any for special comment without doing others an injustice. We note several bearing on war problems, as, for example, that on "Trench Foot," by L. B. Wilson, and that entitled "War's Influence on Medicine," by C. H. Mayo. Among the new operative methods of importance should be mentioned especially Balfour's modification of the Polya operation. Then, too, the advantages of the Kondoleon operation for elephantiasis and lymphedema are well brought out by Sistrunk. Among the special topics whose discussion furnishes articles of particular value or interest are the spleen, pulmonary embolism and epidemic poliomyelitis. There are many other articles of equal importance, but lack of space precludes further comment along this line.

ELECTRO-THERAPY IN GYNECOLOGY. By SAMUEL SLOAN, M.D., F.R.F.P.S.G. Price, $4. New York: Paul B. Hoeber, 1918.

THIS volume comprises sections on electrophysics, electromedical apparatus, the general principles of electrotherapy and the constitutional affections of women in which the latter is indicated. Only Part V is devoted to electrotherapy in gynecology, including diseases of the bladder and rectum. The work is therefore more than it purports to be, *i.e.* more than a mere account of the application of electrotherapy to gynecology, and the author could with propriety have termed it "the principles of electrotherapy with especial reference to gynecology." However, the number of pages is but 292, of which fully 100 are devoted to a tabulation of the author's material. The cuts are neither numerous nor costly to produce, and the price seems excessive.

THE MEDICAL CLINICS OF NORTH AMERICA. Vol. I, No. 4. Boston Number. January, 1918. Price, $10 per year. Published bi-monthly by W. B. Saunders Company, Philadelphia and London.

THESE bi-monthly publications have proved to be a valuable addition to current medical literature. Each number possesses a distinct value of its own in that it embodies features characteristic of the country's leading medical centers. The reader thus obtains authoritative opinions on a great variety of diseases and topics of interest, not only to the strict internist but to the general practitioner as well. In fact, the "clinics" form a veritable post-graduate course brought directly to the physician's office. The Boston number fully maintains the high standard of the previous issues, both as regards the character of its contents and the manner in which they are presented.

The first contribution is from the clinic of Dr. H. A. Christian on a group of patients, illustrating complete and partial heart-block with Stokes-Adams syndrome, digitalis block in auricular fibrillation, and chronic myocarditis. Methods of differential diagnosis, including electrocardiographic tracings, with discussions on etiology, prognosis, and treatment, are dealt with in detail. Dr. E. P. Joslin next presents two cases of severe diabetes and takes occasion to make some timely remarks on the present-day therapy of coma. He draws attention to the appreciable decrease in mortality figures incidental to modern methods. The diagnosis and treatment of empyema in children is the subject of a talk by Dr. John L. Morse. Dr. W. P. Graves, on ovarian organotherapy, cites a few cases of dysmenorrhea and sterility in which definite results seemed referable to the administration of ovarian extracts. Dr. Edwin Locke gives a comprehensive résumé of our knowledge of osteitis deformans, presenting a case of the disease complicated by sarcoma of the humerus. Dr. C. J. White contributes an article on the causes and treatment of premature loss of hair. Dr. F. B. Talbot discusses eczema in childhood from all possible angles, bringing out the rôle of anaphylaxis in respect to etiology. Vincent's Angina is the subject of a clinic by Dr. H. A. Barnes. Dr. A. W. George and associates give an exposition of Roentgen diagnosis of diseases of the upper right abdominal quadrant, illustrated by photographs. Next follows an article on the early diagnosis of pulmonary tuberculosis by Dr. J. B. Hawes; improvements in the diagnosis of chronic ulcer of the stomach and duodenum, by Dr. F. D. White; relation of the teeth and jaws to general medicine, by Dr. K. H. Thoma; pathological hemorrhage, by Dr. George R. Minot; amebic dysentery and associated conditions, by Dr. A. W. Sellards; focal transverse lesions of the cord, by Dr. J. B. Ayer; pyelitis of infancy, by Dr. R. M. Smith; cause and treatment of bronchial asthma, by Dr. I. C. Walker, which includes the recent work done on protein sensitization in relation to this disease. The final paper is by Dr. G. W. Holmes, on the *x*-ray examination of the heart and great vessels. Much of the information contained in this number has been derived from original investigations carried on over a long period of time.

A LABORATORY MANUAL AND TEXT-BOOK OF EMBRYOLOGY. By CHARLES WILLIAM PRENTISS, A.M., Ph.D., Late Professor of Microscopic Anatomy, Northwestern University Medical School, Chicago. Revised and extensively rewritten by LESLIE BRAINERD AREY, Ph.D., Associate Professor of Anatomy in the Northwestern University Medical School, Chicago. Second edition. Enlarged. With 388 illustrations, many in color. Price, $4. Philadelphia and London: W. B. Saunders Co., 1917.

THE death of Professor Prentiss rendered necessary the preparation of the second edition of the Embryology by another. It may be said that the revision, or, rather, the rewriting of Prentiss' Embryology could not have fallen into more capable hands than those of Professor Arey. The first edition was arranged on a definite plan, to combine brief descriptions of the vertebrate embryos which are studied in the laboratory with an account of human embryology especially adapted to the medical student. Arey has followed the general plan and scope of the work and has added a new chapter dealing with the morphogenesis of the skeleton and muscles. The author has succeeded in bringing the present edition into line with the most modern tendencies of embryological advance, and the outcome is a reliable laboratory manual and text-book. A feature of the book is the large number of excellent illustrations which serve to greatly elucidate the printed matter.

THE PRINCIPLES OF HYGIENE. A Practical Manual for Students, Physicians, and Health Officers. By D. H. BERGEY, A.M., M.D., Dr.P.H., Assistant Professor of Hygiene and Bacteriology, University of Pennsylvania. Sixth edition. Thoroughly revised. Price, $3.50. Philadelphia and London: W. B. Saunders Co., 1918.

As this is a sixth edition there is really little to say as to Dr. Bergey's "Principles of Hygiene." It may be said, however, that in the compilation and construction of the book no attempt was made to deal with the question of hygiene in a comprehensive way. The title implies its limitations; it treats of the principles of hygiene. The text of the present edition has been considerably enlarged and revised, a procedure rendered necessary by the progress made in the knowledge of hygiene. Both judicious pruning of and addition to the text have been made in order to bring the work up to date. The result has been satisfactory and the sixth edition provides an excellent reference book with regard to the principles of hygiene.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Fifty-second Annual Meeting, Held at Spring Lake, N. J., June 25 and 26, 1918.

(Special Report to the MEDICAL RECORD.)

THE VICE-PRESIDENT, DR. THOMAS W. HARVEY OF ORANGE, IN THE CHAIR.

Opening Addresses.—The meeting was opened by an invocation by the Reverend Clay Mitchell of Sea Girt and a brief address of welcome by Dr. William K. Campbell of Long Branch on behalf of the Monmouth County Medical Society.

House of Delegates.—After receiving the reports of the officers and transacting routine business, the House of Delegates adopted a recommendation of the Secretary, Dr. Thomas N. Gray, that the County Societies make all the members of their respective societies, who have been or may be engaged in our country's war service, members of the Society for the Relief of Widows and Orphans of Medical Men of New Jersey, by paying their initiation fee and assessments while they are in the service. Resolutions were adopted remitting the dues of all men in the service. The Treasurer's report showed that the Society had purchased two $1,000 Liberty Bonds during the past year, and resolutions were adopted directing the Treasurer to purchase two additional $1,000 Liberty Bonds, and that $1,000 of the Society's money be set aside, subject to the order of the Board of Trustees, any portion of which money was to be used for the relief of any families of the members of the Society who were in the service of the country or in need. Other resolutions were adopted to the effect that the Medical Society of the State of New Jersey send its most hearty greetings to the members of the Society who were engaged in the service of the country, and that the members of the Society recognized their practical patriotism and the great value of the service they were rendering, and wished them the highest possible success in their work and that they might return in health and strength in due time to their work in the home field and their association with the Society's activities.

The Prostate Question.—Dr. TANLEY R. WOODRUFF presented this paper in which he showed that a "Prostate question" did exist. He said that, in the first place, a prospective case should be looked at from the generalized point of view as to whether he should be operated upon at all or not. It was well to remember that an enlarged prostate was the heritage of old age and we must therefore first think over the advisability of doing an extremely dangerous operation on an old man. We must take into consideration his age, his apparent muscular tone, the condition of his blood vessels, his urine, and, not least, his mentality. We must find out if his heart and lungs were going to stand the strain of an operation. If a man had cardio-renal disease, asthma, emphysema, or some complication that would only make the operation a stepping stone to his demise, he should be allowed to live out his expectancy, for he would live only a short time at best. A second point was that an absolute diagnosis was imperative. There were a number of different conditions that would give frequency of urination, hematuria, residual urine, incontinence, and dribbling. The tabetic bladder gave practically the same symptoms as a prostate, and tabetic bladders were often seen without other symptoms of tabes. Diverticulum was also a frequent complication of prostate. All these conditions could be excluded by a preliminary cystoscopic examination of the bladder. A proper cystoscopic examination was essential in diagnosing prostatic obstruction and eliminating complication. For this purpose the straight urethroscope of McCarthy was ideal. The writer had observed a small pedunculated, lobular intrusion, giving a large amount of residual urine with its accompanying symptoms, easily destroyed and the patient cured by burning away with the high frequency current and no further operation was necessary. The instrument might be pulled down into the posterior urethra and the amount of intrusion of the lateral lobes noted. This was most important. Carcinoma of the prostate must be excluded and this was done mostly by the character of the rectal touch. The peculiar stony hardness and the flat, fan-shaped mass felt was almost characteristic. Urethral stricture was frequently missed and the case considered one of prostatic origin. Prostatic hypertrophy and stricture of the membranous urethra were almost never seen together. In prostatic cases attention was usually first directed to frequency of urination and this was nocturnal in character; this differentiated it from stone, which was diurnal in character with nocturnal rest. Pain and tenesmus were later stages. The amount of residual urine was not often as important as its character. A foul, infected residual meant an infected bladder, blood sepsis through absorption of this material, and more or less pyelitis and pyelonephritis. Cabot claimed that this was an advantage to a certain extent, as it acted as a vaccination against post-operative infection. In the absence of pre-operative infection he advised the use of vaccines as a routine procedure to create immunity. A large amount of residual urine should be thoroughly considered, as it was a serious menace to the successful termination of the case. A systolic blood pressure above 155 should be considered too high and particular emphasis should be placed on the pulse pressure as indicative of the myocardial strength. The value of preoperative treatment was already fixed and was the most important part of prostatic surgery. A complete chemical blood examination must be made for urea-nitrogen, uric acid, and creatinin. Cases in which the creatinin was found in amounts of over 5 mg. per 100 c.c. of blood always went bad. The test of the kidney function by phenolsulphonaphthalein should be done in all cases and, in order to be of value, must be repeated from time to time. An excretion of phthalein of less than 25 per cent. in two hours must be looked upon with suspicion. Preoperative treatment consisted in the necessary hygienic and dietary measures to improve the blood and urinary findings as well as the general health of the patient and in the removal of the residual urine, the accompanying systitis, and the lessened kidney function. As a rule, a patient might be considered operable when he had no rise in temperature, when his blood and urine pictures had approached to nearly normal, and when his appetite and general condition were such that he wanted to go home. In discussing the merits of the one and two step methods of prostatectomy it was well to bear in mind that at the present time no urological surgeon did a *bona fide* one step prostatectomy. He always preceded it with a certain amount of catheterization and preoperative treatment. The chief advantage of the so-called one step operation was a wide, clean-cut opening into the bladder, allowing the whole hand to get within its cavity and a consequent proper enucleation of the gland and a good inspection of the wound after its removal. It was to be advised in the younger patients, those having little infection, small residual, good physiques, and good kidney elimination. The two stage operation was not an advised procedure at all. It was a necessity in older men with poor muscular tone, with large residuals, infected bladder, and poor renal output. It became absolutely imperative in those cases admitted with severe bleeding, acute retention, and high temperature, and often with traumatism from attempts at catheterization. The pendulum at the present time seemed to have swung entirely over to the side of the two stage operation. The essayist believed this was a mistake. Certain classes belonged to the one side and certain cases to the other. Personally, the writer's mortality rate with the one step operation had been far less than with the two step method because of the better class of risks. As to which was the better method of enucleation of the prostate, the suprapubic or perineal route, the writer believed the question easy to answer. It was, in his opinion, entirely a personal question, depending upon which method the operator was more familiar with. In behalf of the suprapubic, it might be said that post operative fistulae were less often present, and if present, were less annoying, and that incontinence was rarely seen following it. In behalf of the perineal operation, it was advocated that post operative drainage was in the most natural direction, that the operative

field was always under the eye of the surgeon, and consequently hemostasis was perfect, that post operative shock and sepsis were reduced to a minimum and that the vesical sphincter was untouched. Either operation was no job for the casual surgeon. To do one or the other operation well was sure to bring success. The large, smooth, regular prostatic enlargements the essayist had always taken out suprapubically. The small fibrous nodular, evidently adherent, prostates with periprostatic infiltration, he had removed from below. The writer discussed the vesical sphincter post operatively and stated that it was easily proved that complete destruction of the internal sphincter did not necessarily mean loss of urinary control. Successful prostatectomies might be done by skilled men with any stage operation, either through the perineum or above the pubic bone, if the proper preliminary examinations and preoperative treatments were carried out.

Dr. WILLIAM J. CHANDLER of South Orange said he believed that prostatectomy was one of the best operations we had, the only objection to it being the age of the patient and his consequent inability to withstand any operation. He had never done the suprapubic operation, but always the perineal, according to the method advocated by Dr. Parker Syms. Carcinomas were usually very difficult to remove because the symptoms in the beginning were vague and were often unrecognized or passed by as the usual condition of an elderly man.

Dr. B. V. D. HEDGES of Plainfield said that he had performed fifteen prostatectomies, ten by the perineal route and five by the suprapubic, and fortunately all recovered, all but one had regained control of the bladder, and all had been comfortable. There were three cases that proved to be cancerous and all of these recurred within a year. In patients who came to the physician complaining of frequency of urination and in whom one would suspect prostatic enlargement a great deal was said of removing the prostate, but nothing was said about remedying the condition without operation. Personally he had had a little experience with the high frequency current, having employed it in five or six cases and none of these had come to operation. Other patients had been relieved to the extent that they were quite comfortable after five or six treatments.

Dr. A. H. LIPPINCOTT of Camden said that since he had been paying more attention to preoperative care in cases of prostatectomy the mortality had been greatly reduced. He was fond of the suprapubic type of operation and believed in building the patient up for a big operation; sometimes it took a week and sometimes ten days, while at other times a longer period was required. This was a question of the individual patient.

Dr. W. F. FAISON of Jersey City called attention to the seriousness of suddenly emptying an enormously distended bladder. He had had several instances in which insanity followed the sudden emptying of a distended bladder. In one instance the man remained insane for four months and then recovered. In his opinion the suprapubic operation was the safer one for the surgeon who had not done many of these operations.

Dr. WOODRUFF, in replying to Dr. Hedges' question as to what could be done for cases that were not operated on, said that he believed that if a man had a prostate sufficiently large to cause symptoms he had a prostate sufficiently large to require operation, because if a prostate once became enlarged it would never go down and the tendency was for it to continue to enlarge. He had had no experience with the high frequency current. Reference had been made to accidents that might follow the sudden emptying of the bladder. These were due to the effect on the sympathetic nervous system. He had observed two cases in which death followed catheterization of the overdistended bladder within two hours. Most of the cases of mania following the catheterization of an overdistended bladder were due to uremia.

The Duty of the Family Physician to the Patient Suffering from Headache and Eye Strain.—Dr LINN EMERSON of Orange read this paper. He stated that the points he desired to make clear to the profession were: (1) That there were many headaches which were due indirectly to disorders of the refractive or accommodative apparatus of the eye and that in these instances the brain symptom was often the most prominent and sometimes the sole prominent symptom of the eye troubles, so that while there might be no pain or sense of fatigue in the eye, the strain with which it was used might be interpreted solely by occipital or frontal headache. (2) That the long continuance of eye troubles might be the unsuspected source of insomnia, vertigo, nausea, dyspepsia, biliousness, general failure in health, and even epileptoid convulsions. (3) That in many cases the eye trouble became suddenly mischievous, owing to some failure in the general health, or to increased sensitiveness of the brain from moral or mental causes. While not subscribing to all that George M. Gould said on this subject, he still wished to be counted with him. He did not wish to imply that all men practising general medicine ignored the question of eyestrain, but there were thousands of men who continued to give their patients drugs for the relief of symptoms, when all the patient needed was a *properly* fitted pair of glasses. Of the people about us who needed glasses, at a liberal estimate it might be said that not more than 10 per cent. were properly fitted. While all of those present were agreed that no one should be permitted to fit glasses but an oculist, still they had not succeeded in reconciling the public to this view. If eye strain was suspected and the patient said he had glasses, one should not be satisfied; one should ascertain who fitted them. If the patient was young and no drops were used, he was in all probability improperly fitted. All oculists were not skillful refractionists, and the glasses might be incorrect even when fitted by an oculist of reputation and ability. Most persons were uncomfortable when they first put on proper glasses. In the hyperopic and astigmatic eye, the hypertrophied ciliary muscle failed to relax, the distant vision was then blurred, and if the axes of the astigmatism were not symmetrical some distortion of images was usually present. Even nausea and dizziness might occur. The occasional wearer of glasses was seldom comfortable with them. The constant wearer soon overcame all discomfort.

Dr. A. W. BINGHAM of East Orange said they all agreed with Dr. Emerson that a great many of their patients were suffering from conditions due to or aggravated by eye strain. The difficulty was in determining to what degree the eye strain entered into it, if at all. Every one knew of cases in which a person would go to one oculist after another and get no permanent relief. The speaker believed the patient's physical condition had a great deal to do with this difficulty. If he was tired, or nervous, or had indigestion, he would take a certain degree of correction and when he was rested this would not suit him.

Dr. D. C. ENGLISH of New Brunswick asked why it was that some persons when properly fitted with glasses did not see so well with them as without them.

Dr. WALTER B. JOHNSON of Paterson emphasized the fact that many physicians did not seem to know the difference between the optician and the oculist. It was surprising how many physicians sent patients to the optician. There was not an optician or an optometrist who either knew enough or gave enough time to the work of fitting glasses properly and they seldom knew enough even to fit faces. It made little difference whether the patient had big or little glasses, provided the true center of the lens corresponded with the true center of the eye. If one persisted in using a mydriatic he was pretty sure to have refraction errors, and if there was a refractive error it was possible that the patient would not be able to wear the glasses. It was often better to fit with glasses that did not fully correct until the patient got his eyes into condition to stand full correction. The glasses that he would wear at first might not be those that he could ultimately wear.

Dr. THOMAS S. DEDRICK of Washington, N. J., stated that several of the speakers had said that the medical men did not want the optician and the jeweler doing refraction work. It did not seem to him that the medical profession had ever made a determined effort to prevent the optician and jeweler from doing this work. Now, more than at any other time, we should make a distinction between the oculist and the optician and

optometrist. The Government needed medical men and needed oculists and they did not ask the optometrists to help them out. It would seem that if the Government did not want optometrists to help them out that the legislatures should not license them. But if they were not able to make the legislatures correct this matter, at least the medical men should patronize the oculist in sending out his work.

Dr. B. V. D. HEDGES of Plainfield referred to the reflexes from eye strain. He said he had had three cases in which epilepsy was due to eye strain.

Dr. EMERSON, in closing, said in reply to Dr. English's question as to why some patients did not see as well with the glasses as without them, that these were persons having hyperopic astigmatism who were wearing overcorrected glasses. It sometimes happened that glasses that gave good vision did not fully relieve the patient's trouble and in order to relieve the trouble one had to give glasses that gave a slight blur. Sometimes these patients came back and said that their glasses were causing trouble and then the glasses were made weaker, with the result that the symptoms from which they were suffering were not relieved. Dr. Johnson spoke of drops and gave the idea that when drops were used the patient would not take glasses that fitted. The advantage of using mydriatics and cycloplegics in getting full correction was pretty well established. We used a cycloplegic so that we knew exactly what the degree of refractive error was and then we had that to go by when the patient came for a final fitting. The fitting of glasses could not be done by rule of thumb. One must take into consideration age, sex, occupation, disposition, whether the patient wanted to wear glasses or not, and the oculist who took all these things into consideration was the one who was successful. Many times the patient refused to take anywhere near the proper correction, and if one knew the man and the family, and knew that he would do as you said, you could give him glasses that fully corrected, even though they blurred a little at first, and he would wear the glasses until he became accustomed to them and this would save trouble and expense. If you did not know your patient and followed this course you would come to grief. The patient would keep coming back and finally get tired and go elsewhere. All oculists were not good refractionists and many men did not like the work. Many doctors did not care to be bothered with refraction cases, prefering pathological work. A man's ability as a refractionist was often in inverse proportion to his age and eminence in the profession.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held April 18, 1918.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS meeting was held with the cooperation of the Section on Genito-Urinary Surgery.

Surgery of the Lower Ureter and Bladder.—Dr. JOSEPH F. MCCARTHY spoke on this subject and illustrated his remarks with a lantern slide exhibition. He stated that when requested to participate in the program of the evening, it occurred to him that the work they were then doing on the cadaver in relation to the surgery of the lower ureter and bladder might prove of interest. His feeling up to the present was that the technical aspect of the delivery of the bladder extraperitoneally, and the freeing the latter organ from its peritoneal attachment, had not been brought out with sufficient clarity. In the discussion of the subject he desired it understood at the outset that much of his comment on these subjects would be purely of a speculative character, and was advanced chiefly to furnish food for thought on this altogether difficult subject, and was put forth with the hope of clarifying the matter, and to lay down, if possible, a fairly precise and definitely organized technical procedure. With reference to the exposure of the lower ureter but a few points would be called to mind. The first statement he made was that in their department at the Post-Graduate Hospital, the lumboiliac incision for the exposure of the lower ureter extraperitoneally had been abandoned, and that the vertical incision was now the only one employed, the incision being the customary one of an inch or an inch and a half to either side of the median line and extending from just above the symphysis to the umbilicus over the belly of the rectus muscle and through the sheath of the same, the muscle belly itself being deflected mesially thus coming to the transversalis fascia. In view of the difficulty of incising the transversalis fascia on the moving abdomen, it was worthy of attention that at the lowermost aspect of this incision the transversalis faulted and if the operator would carry his finger towards the lateral wall at this point he would be able to get under this fascia without cutting and thus readily separate it from the peritoneum preliminary to cutting the former the entire length of the wound. An important point to bear in mind was that the transversalis should be cut the entire length of the wound, as thus incised it permitted of the more ready separation of the peritoneum from its bed. The vertical incision was employed because of the fact that the peritoneum stripped up in more orderly fashion, and for the reason that when the peritoneum was sufficiently separated to expose the ureter on its under surface it practically reached the middle line of the body and in large measure assumed the direction of this vertical incision, it therefore seems to expose the lower ureter with much greater facility and at the same time conserves the muscle wall. As to the question of separation of the ureter for more ready delivery of ureteral calculus, considerable diversity of opinion seems to exist. It had been the speaker's experience that the ureter would stand considerable separation from the peritoneum without untoward result. On the other hand, it should be delivered from its environment only to such extent as was essential for the proper conduct of the operation. In connection with the removal of stone the ureter tractor very much resembling an adenoid curette was a very useful instrument. It supported the ureter with the stone contained between the two prongs of the tractor, thus fixing the stone in position, facilitating its removal, and enhancing the convenience of repair. He believed it was always desirable to approximate the sides of the incision with catgut. He could quite understand the logic of failure to approximate the wound edges. Admitting that the urine did escape, there was less liability to cicatrization when proper coaptation was had. Another point of interest he called attention to was the question of drainage. Of course everyone taught that one should keep away from the large vessels with such a drain. Rubber tubing or rigid drainage of any sore was absolutely contraindicated. The large cigarette drain of iodoform gauze was perhaps the most useful of all. It seemed to him that the question of removal of the drainage was important, that it was an error to remove this too early because occasionally hemorrhage ensued even as late as the fifth or sixth day, so that when the drain was removed it should be done very gradually, and should not be completely removed much before the fifth day. He likewise stated that the vertical incision was of advantage in the matter of repair, that all that was necessary was the suture of the sheath of the rectus leaving a small opening below for the emergence of the drain. As to the question of bladder exposure and delivery through the wound, whether it be extraperitoneal or trans-peritoneal, inasmuch as this consideration was more a technical one and dealt less with the subject of indications as to procedure, he would not discuss the question as to whether these cases did better under radical operation or not. Here most communications were extremely vague as to technical procedure. This was rather extraordinary in view of the fact that the procedure was a difficult one technically and the anatomical text books likewise failed properly to bring out these points. Now there were two places to locate the ureter in this exposure. One was in the early delivery of the bladder below and laterally, if one felt for the outer aspect of the promontory of the sacrum. At this point one would almost invariably find the ureter. The other was in the vesico-pelvic fold. When the bladder was completely delivered, the latter was the important place to search, if the bladder was only to be freed laterally the former was the place to search for the ureter. When one had these

structures so delivered, one might really treat the bladder, surgically, as radically as one might wish and with a fair prospect at least of temporary success. Now as to the trans-peritoneal exposure, it seemed to the speaker that the ordinary trans-peritoneal exposure, as outlined in 1885 by Ridigier, and later on by Mayo and Harrington, were insufficient. What should really be done was that upon opening the peritoneum, the latter was stripped from the bladder entirely, after which time it should be closed in an orderly fashion and then the bladder treated extraperitoneally. In other words, it began as an intraperitoneal but actually becomes an extraperitoneal resection. The doctor brought out some minor technical points about the use of the grooved director in the reimplantation of the ureter, and he also called attention to the fact that many years ago, extraperitoneal implantation of the ureters into the rectum was practised; he felt that in the future, probably the near future, a correct technique would be outlined. One of the first real efforts to expose the subject of bladder resection properly from the technical standpoint was the communication of Squier. In this excellent paper he brought out and developed a technique of a really practical nature. It seemed to the speaker, however, that something still remained to be elucidated in the technique of bladder delivery, more particularly with relation to the peritoneal attachment therewith. It was largely with this question in mind that the speaker undertook a series of painstaking studies on the cadaver, and the following points of information had been elicited as the result of this investigation. It was still a question in the speaker's mind as to which was the preferable method of exploration, the extraperitoneal or the intra-peritoneal. The ordinary median incision was carried from the symphysis to the umbilicus extraperitoneally. Here it was usually possible to separate the peritoneum from the transversalis fascia in the middle line. Having done this the latter was incised the whole length of the wound. This would give greater exposure and in some measure promote ease of manipulation and offer a wider operative field. The bladder should be put well on the stretch with clamps and the separation to be successful should be begun below and laterally. This point the speaker wished to emphasize particularly, as separation from above downward was impracticable in the vast majority of cases. Separation from below and laterally, if one got in the right line of cleavage, was relatively easy. Here good transillumination was desirable as it would then outline the vesicoperitoneal attachment. In many instances it was possible to carry the fingers from either side until they met, underneath the urachal and hypogastric attachment. In that event, it was a very simple matter, under vision and with good transillumination and with sharp dissection, to cut the binding structures which were the urachal and the hypogastric attachments, without danger of entering the peritoneum. By any other technique it was practically impossible to separate the bladder without opening the peritoneum, not once perhaps, but maybe in half a dozen places. Likewise it was possible at times inadvertently to open the bladder, which was a real menace, as the opening in the peritoneum means nothing if it were recognized. The technique as previously outlined would obviate this danger and was an orderly procedure based entirely upon anatomical lines. Now when the separation below these attachments was accomplished, the bladder might be freed sufficiently to invert it, that was, to turn the lower side uppermost, whence with gauze the peritoneum might be gradually stripped from below upwards. By this technique and this alone was the bladder best freed. When this was accomplished and the bladder freely movable and delivered out of the wound, one should note on either side of the inferolateral aspect of the bladder the vesicopelvic fold in which one always found the ureter and the vas. Then Dr. McCarthy reviewed the literature with reference to rectal and vesical implantation of the ureter. He said that rectal implantation of the ureter had been attempted in animal experimentation as early as 1851, and Küster, in 1891, did a bladder implantation. He also referred to Coffee's method of employing a sero-muscular flap and buttonholing the mucosa. He said he liked to consider the bladder as being divided into two parts, the trigone and the rest of the bladder. The trigone was least amenable, and the rest of the bladder readily amenable to radical surgery. In the repair of the bladder after resection absorbable suture material only should be used. He never used non-absorbable suture material where it was likely to come into contact with the urine. One little technical point of importance was the use of the groove director, in transplanting the ureter, as by the use of this instrument there was no danger of obliterating the lumen of the ureter. Dr. McCarthy said he thought the pictures clarified the technique, which was a thing the text-books and monographs had signally failed to accomplish.

Perineal Prostatectomy.—Dr. PARKER SYMS made this presentation, which consisted of a motion picture demonstration of his method of performing prostatectomy by the perineal route. He stated that while there was not much originality about the operation the technique had been worked up by him as far back as 1890 and the description of the operation was published in 1900. He was still doing the same operation. He would not go into the details of the history of the operation as all were familiar with the controversy in reference to the relative advantages of the suprapubic and the perineal routes. Albarran used a median perineal incision and did a suprapubic cystotomy for the purpose of putting one or two fingers into the bladder to facilitate the procedure. He felt that it was impossible to reach the prostate through the perineum without the combined operation. The speaker, realizing the disadvantages of the suprapubic operation, as well as those of the combined method, felt that it was an advantage to be able to get down to the bladder without opening it. By means of perineal section one could do this by pushing the bladder and the prostate well toward the peritoneum. He felt also that there was a great disadvantage in upper bladder drainage. In speaking of the technique, Dr. Syms said he had found the retractor devised by Dr. Hugh Young very convenient, but it was possible to deliver the prostate through the perineum without that retractor. In reference to the advantages of prostatectomy, it might be well to recall the fact that, in spite of the advantages in technique, the mortality from suprapubic prostatectomy was a great deal higher than from perineal prostatectomy. A properly performed perineal operation would not be followed by leakage. With the perineal operation the patient should have control of the bladder in a short time after the operation, usually in about eight hours. Again in the perineal operation the drainage was in the line of gravity and was ideal from the point of surgical technique, while the suprapubic operation was far from ideal. After the suprapubic prostatectomy there was a large space left around the neck of the bladder and below and this pocket became filled with purulent urine, and drainage by the suprapubic route had to be up hill. After perineal prostatectomy the bladder sphincter contracted around the tube and the wound was funnel-shaped and led to the surface so that there was no pocket with a collection of fluid, and usually healing was very satisfactory. The speaker said he could recall only two cases in which local infection occurred after the perineal operation. One resulted fatally, and in the other there was a little sloughing of the fascia. When death occurred after this operation it was usually due to renal causes. The operation as a rule required only five, ten, or fifteen minutes for its satisfactory performance. In one case, a man who was considered a very bad surgical risk, the operation from the time of starting until the tube was inserted took just one minute by the clock. In making the enucleation it was important to get just the right line of cleavage and one should do the enucleation with the finger until the isthmus was reached. The gland should be cut at the isthmus to prevent tearing.

Anatomical Results After Prostatectomy.—Dr. A. HYMAN presented this phase of the subject, basing his conclusions on the radiographic finding in a series of observations. He said that the object of the study was to inquire into the mechanism of urination following suprapubic prostatectomy and to note the changes in the topography of the bladder resulting from this operation. A resumé of the literature deal-

ing with the mechanism of the sphincters of the normal bladder showed that considerable discrepancy of opinion still existed concerning the rôles played by the internal vesical sphincter, and the external sphincter, or compressor urethrae muscles. In 1905, a new method of studying the form of the bladder was devised by Völcker. He employed collargol injections combined with radiography, and as a result of his work concluded that the normal bladder, when distended, was invariably broader above than below and was never round. Following this method they also had demonstrated in their collargol radiographs that the internal vesical sphincter was the sphincter that prevented the escape of fluid from the fully distended bladder, and they never observed a funnel-shaped formation. Later investigators had substantiated these findings. The bladder in prostatic hypertrophy showed marked changes in contour in unoperated cases. They varied from small contracted bladder to the large irregular flaccid type. Changes characteristic of prostatic enlargement were to be found at the base of the bladder. Instead of a broad part narrowing at the outlet, the opposite picture was seen. The interior part of the bladder was broad and flat; at times an upward bulging, due to the gland projecting into the bladder, was found. This flattening of the inferior portion of the bladder might be said to be characteristic of prostatic enlargement. The bladder was situated on a higher plane than in the normal, the level depending upon the size of the gland. Its base was found to be opposite the upper border of the symphysis, and more often one or two centimeters higher. The question of sphincter control seemed to the speaker to be decisively settled by the radiographs, which showed conclusively that even in the most extreme distention of the bladder the internal vesical sphincter was the seat of closure. Thirty-eight patients upon whom suprapubic prostatectomy had been performed were selected for this study and in all some 75 radiographs were taken. The most interesting and important changes were to be found in the outlet of the bladder. In a small proportion of the cases only a very slight funnel-shaped formation in the region of the internal sphincter was observed; in a very few cases no changes in the outlet were to be found. It was therefore evident that in this small group of cases the internal sphincter had not been sufficiently injured by the operation to interfere with its proper function. In the great majority of the cases, 28 of the 38 cases, the radiographs showed two distinct cavities, a larger superior one corresponding to the bladder proper and a smaller inferior one extending from the lower margin of the bladder, and continuous with it, to the region of the compressor urethrae. The latter corresponded to the defect left by the removal of the enlarged gland. The contour of this cavity varied from round or oval to a funnel-shaped formation. The latter was more frequent, the broad base being superior. There could be but one interpretation of these findings—the internal vesical sphincter had either been destroyed by the operation or its function so impaired that it could not have any effect in retaining the fluid in the bladder; this had been accomplished by the compressor urethrae muscles. There could be no question that the compressor urethrae muscle acted as an efficient sphincter, for all the cases in this series had excellent urinary control. The writer pointed out the evidence in the radiographs leading one to believe that the sphincter in these cases had either partly regenerated after the operation or was incompletely destroyed by the operation. That the cavity left by the enucleation of the gland was not entirely obliterated and that the internal sphincter was not completely regenerated was shown by the very definite radiographs after an interval of three years. In conclusion it might be stated that: 1. The internal vesical sphincter was the true sphincter of the normal bladder, and of the bladder in prostatic enlargement. 2. The external vesical sphincter, compressor urethrae, was the functionating sphincter after suprapubic prostatectomy in the large majority of cases.

New Operative Procedure in Impassable Urethral Stricture Without Perineal Section.—Dr. FREDERICK J. PARMENTER of Buffalo made this presentation, in which he reviewed the etiology and discussed the length of time elapsing from the inflammation of trauma to the onset of symptoms, the location, types, classification, and symptomatology of stricture. In speaking of the diagnosis, he said that the actual diagnosis could be made only by the endoscope during the period of soft infiltration, as no resistance whatever was offered the passage of the instrument. If hard infiltration were present the bougie a boulé was relied on almost exclusively, for by its use the size, length, and location of the stricture could be accurately determined. Additional information might be secured by stretching the urethrae upon a sound and palpating the degree of thickening from fibrous deposits. The history and symptoms, therefore, were suggestive but not diagnostic. The writer considered the prognosis from the point of view of whether the stricture could be cured or, if it could not be cured, whether the individual could be relieved and the dangers of urinary obstruction avoided. He then discussed the treatment which he stated had a twofold purpose: First, to relieve the urinary obstruction, if such existed; and second, to remove as far as possible all inflammatory deposits in and around the urethra, thus preventing a recurrence of the trouble. In the early stages, especially those of soft and hard infiltration, judicious local applications through the endoscope, together with gentle and gradual dilatation by sounds, Kahlman dilator, etc., were very successful. There were, however, exceptions to this rule. The effects of the dilatations, to quote Oberlander, were a retrograde metamorphosis with reconversion of fibrillary tissue into the ordinary round celled deposit with reabsorption. He also stated that the principles were those underlying Biers hyperemia. Unfortunately many cases had advanced beyond this stage when first seen, and a variable amount of fibrous tissue had been deposited. Treatment in this class of cases would vary from dilatation to internal and finally external urethrotomy, depending upon the degree of contraction and obstruction present. Divulsion and deep cutting with the urethrotome had justly been condemned as unscientific and unsurgical. Gentleness in all methods of treatment, no matter of what description, were the foundation for success. The marked efficacy of either intermittent or continuous dilatation, and the possibility of nearly always being able to carry this out with little difficulty made it the method of choice. Operative methods would be necessary in relatively few cases and were limited to those strictures, large or small, which resisted dilatation because of a preponderance of fibrous tissue or caused urinary obstruction which must always be promptly relieved. Objection has been raised to internal urethrotomy for stricture at or behind the bulb, because of the danger of hemorrhage and sepsis. The writer did not believe these objections were valid provided the dilatation before cutting was never carried above 20 to 22 Fr., and an indwelling catherer relied upon to maintain the dilatation for several days. If no instruments could be passed external urethrotomy must be undertaken, unless the operation devised by the writer was performed. Before deciding that a stricture was impassable Schley had suggested that an endoscope be passed to the site of the stricture and a few drops of adrenalin cocaine solution be instilled through a special blunt pointed needle or 17-18 Brown-Sharp gage. The adrenalin caused the mucous membrane to shrink sufficiently to open a passage through which a ureteral catheter or a filiform often could be passed. If this succeeded either might be left *in situ* acting as an indwelling catheter, or an internal urethrotomy performed. If every attempt failed external urethrotomy must be performed. After reviewing many of the suggestions, modifications, and technique that had been suggested to overcome the difficulty encountered in trying to find the urethra without a guide, and pointing out the dangers of external urethrotomy the author stated that about two years ago the possibility of operating upon impassable stricture through the urethra occurred to him during an endoscopic inspection of a stricture upon which perineal section had been twice performed previously. The excellent view of the operative field caused the experiment to be undertaken. The only knife available was the Otis urethrotome and the blade broke off after the second or third cut. Fortunately internal urethrotomy could then be performed.

Urethral knives were then sought but none answered the purpose. Finally, a three-bladed solid knife, hollow ground, was devised which had answered every requirement. Either gas or cocaine anesthesia might be used, preferably the former. The operation had been performed 19 times, the following technique having been used in 14 cases. A McCarthy endoscope (any straight endoscope would answer the purpose) was passed down to the site of the stricture, the lumen found and pressed firmly against the endoscope, thus affording a perfect exposure of the operative field. The point of the special three-bladed knife was entered into the lumen and the stricture divided for not more than one-half inch. In strictures of this length or less one cut would be sufficient if, however, the stricture was longer the endoscope was gradually advanced, dilating the cut portion of the urethra, or the dilation could be accompanied by the use of the Otis urethrometer. The endoscope was then brought up against the next uncut portion and the same maneuver repeated, and so until the stricture was divided. It was not difficult to keep the field free from blood by using cotton applicators, the hemorrhage usually being trifling. The mucous membrane could usually be made out, thus avoiding the danger of a false passage. It was also important to bear in mind the natural curves of the urethra at the point of operation, so that the endoscope and knife were held in proper alignment before any cutting was done. After the stricture had been divided, a No. 18 soft rubber or straight web catheter was passed through the endoscope and the catheter fastened in place. The bladder was irrigated two or three times in twenty-four hours with 1-6000 potassium permanganate solution, the urine kept acid and the catheter left in from three to five days, after which it was removed and intermittent dilation continued. A brief review of the series of 19 cases operated on by this method showed that 15 had a purely gonorrheal history, one a gonorrheal and traumatic, two purely traumatic, and one gonorrheal and tuberculous. Of the 15 gonorrheal cases the stricture was single and located at the bulbomembranous junction in 10, and in the spongy alone in one. In the remaining four cases two strictures were present, at the bulbomembranous and in the spongy urethra, usually about the middle third. Of the remaining cases, three of the strictures were located in the bulbomembranous and one in the membranous urethra. The average duration in the gonorrheal cases was nine years; in the traumatic cases six and one-half years after injury. The gonorrheal and tuberculous case had lasted twenty years. In ten of the gonorrheal cases the infection was severe. After reviewing the symptoms and complications in these cases, the writer said that two deaths occurred in the series. The first was in a patient 68 years of age who did well until the fifth day after the operation when the retaining catheter slipped out and the interne replaced it with difficulty. The catheter was plugged with blood and no drainage occurred. This was not discovered for nearly eighteen hours, at which time the patient had developed symptoms of septicemia and died within twenty-four hours. The second patient died because of a perforation of the posterior wall of the bladder, which was probably made by the cystoscope and not discovered until autopsy, though five days after the operation the symptoms which developed suggested a bladder perforation. The advantages claimed for this operation were: (1) It was not a difficult procedure if a little time were spent in mastering the technique, and the proper instruments were used. (2) The period of convalescence was brief, so that prolonged stays in the hospital and absence from work were unnecessary. (3) No suprapubic or perineal opening was required with the subsequent danger of fistula. (4) The drainage afforded by the indwelling catheter was as good as by perineal section. (5) The continuous dilation by the catheter for several days accomplished wonders and rendered aftertreatment less painful and more easily carried out.

Dr. McCarthy said that Dr. Parmenter's point was well taken and they, the genito-urinary surgeons had been accustomed to getting a good deal of information from Buffalo, but he was inclined to think that the technique which Dr. Parmenter had presented had a rather limited application and that it was only suitable to a small group of cases, those, in fact, in which the stricture would admit a No. 18 French sound. He did not quite see how one could be certain of confining his operation absolutely to the urethral canal when using this sharp instrument. If a filiform extension were adapted to the end of the three-bladed knife he thought it would serve fully as well and there would not be so much danger of doing damage to the urethra.

Dr. Martin W. Ware referred briefly to a method he had used, which received no mention in recent textbooks but which had been employed for a number of years in France, which embodied all the ideas presented by Dr. Parmenter except the use of his particular knife which was directed under the guidance of the eye through the endoscopic tube. This much simpler procedure was the method of internal urethrotomy devised by Albarran. The method was illustrated in a drawing by Dr. Ware. After a stricture had been determined to be sinuous or tortuous a filiform was introduced into the bladder. The Maisonneuve cutting instrument was screwed to the filiform. The division of the stricture accomplished, the Maissoneuve was unscrewed and a conductor 18 inches in length substituted. Over this combined filiform and conductor as a guide, a woven catheter was passed to remain as indwelling and the guide removed. It was thus apparent that after the stricture was cut, at no time was the raw surface ever exposed to the urine. This was the crux of the whole operation. The procedure, as demonstrated by Dr. Parmenter, embodied also the idea of dividing the stricture by sight. But one could not look down a tortuous passage and would have to be guided by the sense of touch none the less. Hence with the aid of optical instruments one was still groping, if not in the dark at any rate in the light. It therefore seemed to him that only in the strictures of small extent pictured this evening this particular operation had a limited application.

Dr. Parmenter, closing the discussion, said that he had covered the English literature in the Index Medicus for the last five years, but had not covered the French or the German literature, which would explain how he had missed the Albarran technique. He felt quite certain when this operation was presented as original it would be discovered that someone else had previously tried a similar method, but so far such a technique could not be found in the recent literature; nor was it known to a number of urologists with whom he has conversed. He was very glad to have his attention called to Albarran's method, which was in some ways similar. The only claim to originality which he desired to make was the operative technique, because the idea of cutting strictures through the endoscope was not new. This was, however, the only definite description of any operative procedure. Replying to Dr. McCarthy's remark that he thought an 18 catheter too small adequately to drain an infected bladder, it was always possible after the cutting to dilate the stricture to any size desired and place a catheter as large as a 20 or even 24, and thus secure good drainage. He only advocated this operation for impassable stricture instead of perineal section. Thompson Walker had mentioned the fact which these observations confirmed, namely, that the orifice of the stricture usually pointed towards the upper wall of the urethra, which made it difficult to pass the catheter or filiform without exposing the orifice through the endoscope. Buerger had recently mentioned the same point, and felt that a filiform should be introduced by direct vision, rather than time spent in a blind search. Replying to another point of Dr. McCarthy's, namely, that the point of the knife should be dull, Dr. Parmenter said that if the endoscope was passed and held firmly against the stricture—which was done by making traction upon the penis and pressure upon the endoscope—thus making the cutting in absolute alignment, he had never made a false passage, as the mucous membrance was always present to act as a guide. In concluding, he said he wished to repeat that he had found the method described in his paper to work very satisfactorily; that he had never, up to the present, had any trouble with its execution, and, after a considerable experience with perineal section, he was convinced that this method was far superior to it.

Stated Meeting, Held May 2, 1918.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS program was arranged in cooperation with the Laboratory of the Board of Health, Dr. William H. Park, Director.

Specific Prevention of Poliomyelitis.—Dr. H. L. ABRAMSON presented this paper, in which he brought out the salient facts in work extending over two years, the object of which was the development of a method for protection against poliomyelitis. He stated that their first effort in this work consisted of an attempt to adapt the virus of poliomyelitis to the rabbit. After a rather extensive experience with the rabbit it was decided that this animal was not suited to the work. The material used in the rabbit work was derived from the brains and cords of human poliomyelitis, of monkey poliomyelitis of the 1916 epidemic, and of monkey poliomyelitis produced by a highly potent Rockefeller strain. Of a total of 145 rabbits inoculated and subinoculated by various methods, used singly or in combination, only the following exhibited paralytic symptoms that might have been construed as experimental poliomyelitis; four in the first generation; four in the second generation, and once in the third generation. Fifteen rabbits were subinoculated with the fresh brain and cord of the rabbit of the third generation without production of paralytic phenomena. Efforts in this direction were then discontinued and attention turned to the use of monkeys of the rhesus variety, the high susceptibility of this animal to experimental poliomyelitis having been amply demonstrated. The virus used in this work was obtained from the Rockefeller Institute and was of such potency that 0.05 per cent. of the supernatant fluid of a centrifuged five per cent. emulsion inoculated into the brain of a monkey produced a lethal poliomyelitis infection. This virus was very reliable. Instead of using live virus in increasing small doses over a prolonged period of time, or a single large dose subcutaneously, it was determined that the injection material ought to be modified or attenuated in some manner so as to remove any possible harm from the method itself. Also, to render it suitable to use in time of epidemic, it was decided that the time consumed in administration ought to be as short as possible, consistent with the production of a degree of immunity sufficient to protect against a reasonable exposure to the disease. Their first effort to attenuate the highly potent monkey virus by exposure of a 10 per cent. emulsion to 0.3 per cent. formalin for three hours was not satisfactory. It was then decided to try out the effect of heat as an agent for the attenuation of the virus. The virus, in 10 per cent. emulsion, was exposed to the effects of heat in two ways: In one the virus was subjected to 55° C. for one-half hour for each of 10 injections, used on successive days. This represented the use of killed virus. In the other the virus was gradually attenuated by being subjected to heat as follows: The first day's injection 55° C. for one-half hour; the second day's the same; the third day to 45° C. for one-half hour, the fourth day to 37° C. for one-half hour; on the fifth and last day it was injected unheated. The material was injected subcutaneously in doses of five c.c. Twenty days after the completion of the series of injections the animals were bled by cardiac puncture in order to determine the presence or absence of neutralizing substances for poliomyelitis virus. This was done by exposing five per cent. virus emulsion to the action of the serum in the proportion of 1.1 for two hours at 37° C. and 22 hours in the ice-box. These mixtures were then inoculated intracerebrally into normal monkeys. On the twenty-first day after the completion of the series of preventive inoculation, the treated animals were subjected to an intracerebral test of from three to six lethal doses of the same emulsion used in the neutralization tests. Normal control animals were inoculated with the same emulsion and the same dosage. Only three animals were treated by the killed virus method. There were no untoward effects. Two of these animals failed to resist the intracerebral test inoculations, one with six lethal doses, the other with three. These animals died of typical experimental poliomyelitis with an incubation of six days. The third animal developed paralysis after an inoculation of fourteen days, which progressed until all the limbs were involved; this animal finally recovered. Of the sera of these animals, all exhibited evidences of neutralizing power, but not in equal degree. Two normal control animals succumbed with an incubation of five and six days respectively. Eleven animals were subjected to injections with virus attenuated by graded heat. Even though the final injection was not modified by heat none of these animals showed any untoward effects from the treatment itself. Of eight of these animals five resisted successfully a multiple lethal intracerebral injection of this highly potent virus. Five of the tested animals received six lethal doses. Of these three were protected. Three animals were tested with three lethal doses and of these two were protected. Dr. Abramson described the method of testing animals for neutralizing substances, In summarizing he said that the killed virus methods produced some immunity but not a high degree. The sera of animals so injected contained neutralizing substances, and one out of three survived the multiple lethal intracerebral test inoculation, but with complete paralysis. The five-injection method, involving the use of virus subjected to graded heat with a final injection of unheated material, produced protection of a considerable degree against an unusually severe method of testing. The sera of all these animals contained neutralizing substances in varying degree. The outstanding facts of this work were that this latter method had produced no ill effect as a result of the treatment itself; that the injection of graded attenuated material had prepared the animal to take care of the final injection of live virus; that it had produced sufficient immunity to protect animals against a multiple intracerebral dose of a highly potent virus which was a hundredfold severer exposure than that to which persons were subjected in the natural mode of infection; that it produced neutralizing substances in the blood in such concentration as should be amply able to combat the comparatively mild infection which might lodge on the mucous membrane of persons exposed to poliomyelitis. Furthermore, the series of injections were completed in five days, which rendered it highly practicable in time of epidemic. The injections could be prepared from glycerolated virus, which might be kept on hand over a long period of time without deterioration and required only moderate laboratory facilities for its preparation.

A Rapid Method for the Determination of the Type of Pneumococcus in Pneumonia Sputum.—Dr. CHARLES KRUMWIEDE presented this communication, in which he stated that the sand method, devised by Mitchell and Muns, as well as observations of their own, made in an attempt to determine the earliest time at which precipitable pneumococcus antigen was demonstrable in the washings from the peritoneal cavity of mice inoculated with pneumonia sputum indicated that pneumonia sputum contained considerable soluble pneumococcus substance. This fact together with the knowledge that sputa of pulmonary origin contained albumin suggested the following rapid method of determining the type of pneumococcus. The sputum was poured into a test tube which was placed in boiling water for several minutes, when, if the sputum were of satisfactory quality, it would coagulate more or less firmly. The clot was broken up and, if no fluid separated from the clot, a small amount of saline solution was added. The test tube was again placed in boiling water so that the soluble pneumococcus substance in the clot would be extracted by the hot fluid. The extract was then cleared in the centrifuge and this fluid added to the type sera. The lighter extract was floated over the sera so that the precipitate appeared as a white ring at the point of contact, should a reaction occur with one of the type sera. The reaction was usually evident after five minutes' incubation in the water bath, at a temperature of 45° to 50° C. With positive sputa the readings were usually made within fifteen to twenty minutes after the receipt of the specimen. The success of the method depended upon the quality of the serum submitted. About 3 c.c. of sputum was desirable for the test. The speaker stated that of 183 sputa received in their regular routine 129 had been satisfactory for this method of testing. Of the good specimens, 99 contained a mixed type and about 95 per cent. gave a promptly positive reaction. Of the

poor specimens, 16 contained fixed types, but mouse inoculation was necessary to determine this. Of 50 sputa containing a Type I pneumococcus, 40 were satisfactory for this method and 39 gave a positive result. As Type I serum was available for therapeutic purposes, they were able, in these instances, to send the serum back with the messenger delivering the sputum, which resulted in the earlier administration of the serum.

Complement Fixation in Tuberculosis; Technique.—Dr. M. A. Wilson presented this communication. She stated that all the reagents were used in one-tenth the classical Wassermann volume. The fixation period was one hour, at 37° C. The patient's serum was inactivated for thirty minutes at 55° C. Two-hundredths and one-hundredth of the undiluted serum were used in the test and four-hundredths for the control of the anticomplementary reaction. Two antigens had been used, one made from twelve stock cultures of human tubercle bacilli, the other from strain 305 (used for tuberculin production). These antigens were suspensions in 9 per cent. saline of dried bacilli from which all constituents soluble in alcohol and ether had been removed. The antigens were grown in glycerine broth. The polyvalent antigen cultures were grown for three weeks, and the monovalent for three months. The broth cultures were killed by heating in the Arnold sterilizer for one hour. The cultures were then filtered through filter paper, the filtrate discarded, and the residue placed in absolute alcohol, in the proportion of one volume of residue to ten volumes of alcohol. This mixture was shaken thoroughly by hand, and placed in the icebox for three weeks. It was then filtered through paper, the filtrate discarded, and the residue washed in absolute alcohol. After this it was centrifuged and washed in ether, centrifuged again, and the ether discarded. The centrifuge tube containing the residue was plugged and placed in the dark, at room temperature, over night. By this simple procedure the residue was dried in twenty-four hours. The dried powder was emulsified in a large mortar with 0.9 per cent. saline in the proportion of one gram of powder to 200 c.c. of saline. This gave a concentrated emulsion convenient for storing as a stock antigen. The emulsion was heated for one hour at 80° C. The antigen was now ready for use, and was standardized to be used in such a dilution that one-tenth c.c. would contain two standard fixation units and one-quarter or less of the anticomplementary dose. The unit was determined by titrating varying amounts of the antigen with 0.01 c.c. of a known positive tuberculosis serum and two hemolytic units of a complement known to be potent for tuberculosis fixation. The standard dilution of these two antigens was 1:50. This made a final dilution of 1:10,000 dried bacilli. These antigens were not anticomplementary. They had given uniform and constant fixation reactions. The tests reported showed that they were specific and stable. They were made ten months ago and were perfectly efficient today. For the complement, guinea pig's serum twenty-four to forty-eight hours old, pooled from six to ten guinea pigs, was used. Before pooling, the serum from each pig was tested for its hemolytic strength, for antisheep amboceptor, for anticomplementary reaction with a heterologous serum and for fixability with the combination of tuberculosis antigen and tuberculosis serum. This last test was emphasized as essential, if uniform results were to be obtained with the different lots of complement. It had been proven beyond a doubt that although a guinea pig's serum might react perfectly in all other respects, it might fail to be fixed by tuberculosis antigen and serum. Of the pigs they had tested 64 per cent. failed in fixability. The pooled serum was titrated with cells sensitized with three standard units of amboceptor. The reaction was read at the end of fifteen minutes. Two hemolytic units were used in the tests. The indicator for the fixation reaction consisted in 0.1 c.c. of a five per cent. suspension of sheep cells sensitized with three standard units of antisheep amboceptor. The controls for the diagnostic fixation reaction comprised an antigen for anticomplementary reaction, for specificity and for potency; a serum for anticomplementary reaction for specificity and for natural antisheep amboceptor; a complement for stability (system control), and finally sensitized cells for testing the stability (reading the control). Dr. Wilson presented the results of tests of serums from 344 cases of known tuberculosis, which showed that among the cases of active tuberculosis 67 per cent. gave a strongly positive reaction, 25 per cent. a weakly positive reaction, and 8 per cent. a negative reaction. Of the cases of bone and joint disease, 12 per cent. gave a strongly positive reaction, 10 per cent. a weakly positive reaction, and 78 per cent. a negative reaction.

Of the cases of tubercular glands, 35 per cent. gave a strongly positive reaction, 20 per cent. a weakly positive reaction, and 42 per cent. a negative reaction. Of the poliomyelitis fluids, 100 per cent. gave a negative reaction, and of subjects having no symptoms of tuberculosis, 100 per cent. gave a negative reaction. The conclusions reached were that all guinea pig serums were not efficient for tuberculosis complement fixation and that the serum of each guinea pig should be tested for fixability with tuberculosis antigen plus tuberculosis serum before pooling the complement for diagnostic tests.

The Complement Fixation Reaction for Tuberculosis; Clinical Results.—Dr. H. Von Wedel presented this contribution, in which he related his observations made in the course of 1,078 complement fixation tests on 29 specimens of blood serum taken from cases with no clinical history of tuberculosis and from patients with active, inactive, and primary pulmonary tuberculosis. This study was made in conjunction with Dr. Wilson in the Board of Health Serological Laboratory. The cases were all from the Westchester County Hospital, the White Plains Hospital, and the New Rochelle Hospital. The method of setting up these reactions was exactly the same as Miss Wilson had described, with two important modifications: The regular amount and double the regular amount of patient's serum originally advocated by Wassermann was used, and the reactions were set up one day after the specimen was removed from the patient and every week for four or five weeks with an interval of seven days between each test. Apparently the icebox fixation gave no better results than the one hour water bath fixation. The two hour water bath fixation, the writer believed, would give uniformly positive results. However, they could not state positively which was the best method of fixation. A large number of comparisons would be made in the near future to determine this question. The writer's experience in making a large number of Wassermann tests and also with the complement fixation test in tuberculosis showed that an appreciable number of cases gave definite positive results with double the amount of serum and negative or doubtful reactions with the single amount of sera. The cases tested were classified as belonging to the seven following types: (1) Primary cases, or those having few physical symptoms and no tubercle bacilli in the sputum, or only after examining many specimens by the antiformin method. (2) Active cases, or those expectorating tubercle bacilli, and with incomplete or no walling off of the tuberculous area. (3) Active cases in the last stage. (4) Partially inactive cases, that is cases expectorating tubercle bacilli but having very marked fibrous formation with the consequent complete walling off of the disease from the body proper. (5) Inactive cases. (6) Cases reported as possibly suspicious, but expectorating no tubercle bacilli and having no symptoms of tuberculosis. (7) Non-tuberculous cases. Of Type (1) all gave positive results. Of 49 Type (2) cases, 46 were positive. Of 11 Type (3) cases, three were positive, three doubtful, and five negative, giving 27 per cent. positive, and 27 per cent. doubtful. Of 19 Type (4) cases, six were positive, five were doubtful, and eight were negative, giving 31 per cent. positive, and 26 per cent. doubtful results. Of 12 Type (5) cases, three were positive, nine were negative, giving 25 per cent. positive results. Of four Type (6) cases, all were negative, giving 100 per cent. negative results. Of 92 sterile Type (7) sera, all were negative. In comparing the temperature, pulse, and respiration records of the patients with the complement fixation reactions, it was found that a large percentage of cases having high temperature and respiration records gave a strong positive reaction and, *vice versa*, a large percentage of cases having low temperature and respiration records gave negative reactions. N. J. Corper concluded that in the presence of a positive

Wassermann reaction, the presence of a positive complement fixation test for tuberculosis was of no practical value. He had also stated that the most reliable investigators conceded that a suspension of living tubercle bacilli was the only one of the many antigens used that was of specific value, but that the objections to the bacillary emulsion were the small leeway between the antigenetic and the anticomplementary dose, the turbidity produced in the tubes, and the fairly high percentage of non-specific reactions. To all these statements the writer took exception. First because in his series of cases there were 26 specimens from patients that gave positive Wassermann reactions but with no physical symptoms of tuberculosis; none of these gave any cross-fixation with the Wilson tuberculosis antigen. Secondly, in no instance did he get a positive reaction, using double the regular amount of sterile patient's serum, in his entire series of non-tuberculous cases. Thirdly, he had never found the Wilson antigen to be anticomplementary in four times the dose used in the test, if the antigen was heated at 55° C. for one-half hour just before using. Fourthly, his results in the active tuberculous cases gave 98 per cent. positive reactions. Fifthly, the very slight turbidity produced by the antigen in no way interfered with the reading of the results. Dr. Von Wedel concluded as follows: (1) The tubercle bacillus antigen which was used by them was not anticomplementary in four times the amount necessary to give positive fixation results with sera from the majority of active tuberculosis cases. (2) Pooled complement from at least six guinea pigs should be used in making the tests, or the complement from single pigs should be tested for its complement fixation value with known positive sera. (3) Double the original Wassermann amount of patient's serum should be used. (4) No report should be made until the sera was tested, after having been kept under sterile conditions in the icebox for from four to six days, but preferably six days. (5) The writer's results seemed to indicate that if the aforesaid modifications of the original complement fixation tests were used 100 per cent. of non-tuberculous cases would give absolutely negative results; nearly 100 per cent. of the primary and active cases would give positive results, with the exception of the dying cases, and about 25 per cent. of the partially inactive and negative cases would give only weak positive results. Before any definite conclusions could be drawn a much larger number of tests would have to be made. He hoped to report on the results of about three thousand tests in the fall.

The Meningococcus Carrier Problem from the Laboratory Standpoint.—Dr. ANNA W. WILLIAMS presented this subject. She stated that in the Bureau of Laboratories they had been carrying on investigations in regard to the detection of meningococcus carriers chiefly from two standpoints: (1) That of developing a method of making accurate and rapid diagnoses that could be of practical use in examining large series of cases such as occurred when meningitis appeared in camps. (2) That of determining the types of meningococci found in carriers and their relation to case strains. This work was undertaken because of the request for aid in the hunt for carriers in certain camps, aviation fields, and ship stations in the vicinity of New York City. They began by testing out the different culture media recommended. This was done, not by seeding the plates of media with stock cultures of meningococci, but by using freshly isolated cultures, and these in one to fifty dilution, in order to make the conditions more nearly approach those met with in the primary culture from the case. The difference in the results from testing in this way over those from testing with stock cultures was marked. Among the media tested were the so-called hormone medium recommended by the Lloyds in England and Dr. Huntorn in this country, which had been found to give, on the whole, the best results, but only when a small amount of blood was added to it, a drop to a plate. Different lots of this media varied in their ability to give good growth, and they therefore recommended that every lot of it be tested by planting plates of it containing blood and plates without blood with a 1-50 dilution of two recently isolated strains, and that only those lots be used for this work that gave at least a moderate growth in the plates containing no blood. This medium always gave an abundant growth when blood was added. The procedure consisted in taking the cultures in the West tube, spreading on one plate, incubating for 20 hours, and then making the macroscopic slide agglutination titer of the serum, and recording the result. A comparison of this method with other methods showed that it possessed the advantage of shortening the time to twenty-four hours and the procedure and apparatus were much simpler. In reference to the second point, that of determining the type of meningococcus and its relation to the case strains, Dr. Williams said this part of the work was the more important part for helping to decide how necessary it was to try to weed out and isolate meningococcus carriers, and it had only just been begun. They had two groups of strains which they were studying in connection with the case strain in each group which they thought might furnish interesting data. One of these groups came from an aviation field, the case developing in one of three carloads of soldiers coming from the South. The patient had given slight symptoms for a day before arriving and the soldiers from all the cars mingled freely at several stops on the way. The immediate contacts of this case, so far as could be determined, were 30, and among these there were 8 carriers, or 23 per cent. In the rest of the squadron, numbering 187, there were 21 carriers, or 11 per cent. The entire number examined gave 13 per cent. carriers. The second group came from a receiving ship station. The whole number examined was 293, among whom 21.5 per cent. were carriers. The difference in the percentage of carriers in these two groups was significant. The question as to the presence and significance of types among meningococci was still undetermined. Gordon and his coworkers claimed that there were four distinct types of pathogenic meningococci demonstrated by the absorption of agglutinins. Griffith and others thought that there were only two rather indefinite types. The last Rockefeller division was three groups. Gordon stated that those strains that did not fall into his four types were probably non-pathogenic and that as a large percentage of non-contact carriers did not fall into these groups, many non-contact carriers were probably non-pathogenic and therefore did not need to be isolated. Griffiths and others, on the other hand, believed that every strain of gram negative cocci with cultural and fermentative characteristics similar to those accepted as typical of meningococci was potentially, at least, pathogenic, and that it should be treated as though fully pathogenic. If Gordon's contention proved to be correct it would simplify matters a good deal from the standpoint of an efficient army, but it would increase the complexity of the laboratory test. In the study of their own groups by the method of absorption, Miss Cooper, who was doing his work, found that in their first group the case strain and nearly half the contact strains fell definitely into Gordon's Type I group, one-fourth belonged to Type III, the group most nearly related to Type I, and the rest either belonged to Type IV (not yet tested with Type IV serum) or were heterogeneous. These results seemed to bear out Gordon's claims. The study of the other group had already presented a complication which showed how much study was still needed to clear up this problem. The case strain was a practical non-agglutinable strain. Serum produced from this strain, though it did not agglutinate its own strain, agglutinated Gordon's Type II strain in very high dilution. This strain might prove to be a member of a sub-group of Type II. This was an indication that Griffith might be more nearly right than Gordon and that the procedure of determining the types by absorption might be unnecessary.

Immunization of the Infant Against Diphtheria.—Dr. WILLIAM H. PARK and Dr. ABRAHAM ZINGHER made this contribution, which was presented by Dr. Park. Dr. Park stated that the results obtained during the past three years had shown not only the possibility but the feasibility of immunizing the child population against diphtheria. With the second six months of life the child entered upon its period of danger and required protection. The immunity conferred by the mother disappeared generally during the second six months of life, but in some children not until the end of the second year. One therefore could not depend on a negative Schick test indicating a permanent immunity

until after this time. The injection of the standard toxin-antitoxin dose into children who were passively immune, because of antitoxin transferred from the mother or by its injection, did not give as much of an immunizing stimulus as when injected into those having no antitoxin. A fourth injection of a less neutralized mixture would probably successfully overcome this deficiency. At the present time they were recommending somewhat different procedures in institutions and in the general population. The procedure in institutions was as follows: Inmates six months or more in age should be Schick tested. If positive they should be immunized by injecting subcutaneously three doses of toxin-antitoxin mixture. The injections were given at intervals of about one week. The amount for those under one year was one-half c.c. of the standard Health Department mixture. For those who were older one c.c. was given. Those giving a negative Schick test were retested every three months up to the third year because of the gradual loss of passive immunity in many. Those giving a positive reaction at any test were immunized. This work, carried out by Dr. Blum, had given an immune group of infants, as shown by the Schick test and the absence of diphtheria. The procedure adopted with infants and young children in their homes consisted in giving every individual three injections, or a preliminary Schick test could be done and only those not immune given treatment. Those who were immune under three years of age, and especially those under two years of age, should be Schick tested every six months because of the possibility of the immunity being temporary only, due to the antitoxin conveyed through the mother. After the administration of the immunizing doses of toxin-antitoxin immunity developed in from three weeks to three months and lasted more than two and one-half years. Only time would tell whether the immunity would be permanent or not and they would continue to test children who had been immunized and to report on the results from year to year. If observation showed that a number of children lost their immunity, the Schick test would show which should receive another series of injections. In primary schools the children should be Schick tested on their admission and those giving a positive Schick test should be injected. Mothers should be urged to have their infants tested for immunity at the end of the first year and the positive cases immunized. The Health Department inspectors and probably the nurses could administer the immunizing doses. Dr. Park exhibited charts showing the results of Schick tests and active immunization in the 1,169 children in the Hebrew Orphan Asylum and of 760 children in the Convent of St. Dominic. The many thousands of injections made without producing any deleterious reaction, demonstrated the harmlessness of the procedure. Among the 1,169 children in the Hebrew Orphan Asylum, 14.4 per cent. were non-immune, and among the 760 children in the Convent of St. Dominic exactly the same percentage were found to be non-immune. Experiments had been conducted to ascertain the immunity conferred by one, two, and three injections of the toxin-antitoxin and the result when the three injections were given at the same time in scattered regions of the body. They had found that by giving the three injections 98 per cent. of non-immunes became immune; by giving two doses of the toxin-antitoxin, about 90 per cent. became immune, and by giving one dose only about 75 per cent. developed immunity. Most of their work had been done with the three injections. The time required for the development of immunity ranged from two weeks to twenty-one months.

Dr. ABRAHAM JACOBI, in response to an invitation to discuss the papers of the evening, said that after he had heard all that these people had to say he had nothing to add. He had given some attention to laboratory work a long time ago before these people were alive, between 1860 and 1880, but since that time it always appeared to him that he knew nothing about that line of work. There was only one thing he wished to say and that was that he had been much delighted with what he had heard to-night and that it had struck him that these men and women had particular and good reason to speak here as they belonged to the Health Department. In his opinion the Health Department, because of the work it was doing, was quite worth while, and he wanted the audience to recognize that it had a duty to see that the Health Department was not changed in its most important aspects. He hoped they had been reading the newspapers and knew what had been said by men in a position to know the value of the Health Department. These things were worth while saying not only privately but publicly and wherever they were. Whatever any of them could do to hold up the hands of the Health Department they certainly should do.

Dr. ISRAEL S. FEINBERG made a few remarks in reference to the value of the work the Health Department was doing. He emphasized the fact that not only the city but the entire country owed much to Dr. Park. Other countries had always paid tribute to his scientific proficiency. As he had listened to the papers his mind had harked back to the time when he began to practise medicine in this city and the conditions that prevailed at that time, and as he had listened to Dr. Jacobi, the Nestor of Medicine, he again pictured to himself the children dying of diphtheria and with acute meningitis of the most virulent type, and recalled the frightful suffering they experienced, and he thought of the prevalence of typhoid fever in those days and of the helplessness of the practitioner in the presence of these diseases. The picture had changed owing to the splendid work of the Health Department; and yet today they were confronted with the possibility of a return to those conditions through an overthrow of the organization of the Health Department. Dr. Feinberg made a motion for a rising vote of thanks and appreciation to Dr. Park.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE AMERICAN HOSPITAL OF THE TWENTIETH CENTURY. By EDWARD F. STEVENS, Architect. 274 pages. Illustrated. Price, $5.00. Published by Architectural Record Publishing Company, New York.

HYGIENE FOR NURSES. By NOLIE MUMEY, M.D. 160 pages. Illustrated. Price, $1.25. Published by C. V. Mosby Co., St. Louis.

A TEXTBOOK OF PHYSIOLOGY FOR NURSES. By WILLIAM GAY CHRISTIAN, M.D. 168 pages. Illustrated. Price, $1.75. Published by C. V. Mosby Co., St. Louis.

SURGICAL AND WAR NURSING. By A. H. BARKLEY, M.D., M.C., F.A.C.S. 208 pages. Illustrated. Price, $1.75. Published by C. V. Mosby Co., St. Louis.

NURSING IN DISEASES OF CHILDREN. By CARL G. LEOWOLFE, M.D. 314 pages. Illustrated. Price, $2.50. Published by C. V. Mosby Co., St. Louis.

MILITARY HYGIENE AND SANITATION. By FRANK R. KEEFER, A.M., M.D. Second edition; reset. 340 pages. Illustrated. Price, $1.75. Published by W. B. Saunders Co., Philadelphia and London.

THE ORTHOPEDIC TREATMENT OF GUNSHOT INJURIES. By LEO MAYER, A.M., M.D. 250 pages. Illustrated. Price, $2.50. Published by W. B. Saunders Co., Philadelphia and London.

SURGICAL TREATMENT. By JAMES PETER WARBASSE, M.D. 947 pages. Vol. I. Illustrated. Price, $30 per set of three volumes and index. Published by W. B. Saunders Co., Philadelphia and London.

SOME OBSERVATIONS AND RESULTS IN THE TREATMENT OF FOUR HUNDRED CASES WITH RADIUM.*

By REX DUNCAN, M.D.,

LOS ANGELES.

ATTENDING RADIUM THERAPEUTIST AT THE LOS ANGELES COUNTY HOSPITAL; ATTENDING CLINICIAN IN THE RADIUM CLINIC OF THE GRAVES MEMORIAL DISPENSARY OF THE LOS ANGELES MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA; MEDICAL DIRECTOR OF THE RADIUM INSTITUTE OF LOS ANGELES.

THE purpose of this paper is not to discuss in detail the comparative value or results of radium therapy in selected groups of cases. These have been, or will be, reported fully at such time as the treatment of a sufficient number, after proper interval, permits of forming more definite conclusions as to the results accomplished. Rather would I consider in a general way some observations and results gained from the careful study and treatment of more than 400 cases representing a considerable variety of pathological conditions.

Without entering into a detailed discussion of the subject at this time, I wish to repeat that radioactive substances, of which radium is the principal one used for therapeutic purposes, differ very greatly in their physical characteristics, mode of application, and the effect produced upon the body tissues, from the *x*-ray, violet-ray, and other so-called artificially produced rays. An assumption of their similarity emanates, almost without exception, from men with more or less familiarity with these agents and little or no knowledge or experience with radium.

The rays emitted by radium are of three distinct kinds, known as the Alpha, Beta and Gamma rays. From the Roentgen-ray tube are emitted only rays which are similar to, but by no means identical with, the Gamma rays of radium. *X*-ray therapy is dependent entirely upon a certain selective action of these rays. With radium, we may utilize either the markedly selective, or the destructive, effect of either the Beta or the Gamma rays. The delay in healing and serious consequences following the destructive effect of the *x*-ray are too well known to require comment. With radium, in the treatment of many superficial conditions, the Beta rays are employed for both their selective and destructive effect, which heals promptly and with good cosmetic results. Of my cases, the large number that have responded promptly to radium therapy, after receiving little or no improvement from prolonged *x*-ray treatment, is alone sufficient to demonstrate the decided difference in the therapeutic effect of these agents.

The dose and technique of application of radium necessarily depend upon the location and characteristics of the pathological condition under consideration, as well as the general condition of the patient. A thorough physical examination of all cases, together with such laboratory analysis as may be indicated, has prevented many errors of omission and commission, and should precede the application of radium, or any other therapeutic agent.

I have discussed in detail in previous papers the histological changes produced by radium, and for the sake of brevity will call attention to a few salient facts only. New and imperfectly formed tissues and cells are more susceptible to radium than are normal tissues. Janeway and Ewing have shown that one-fourth the dose required to destroy normal epithelial cells will permanently destroy carcinoma cells. Endothelial cells are especially susceptible to radium, as evidenced clinically by the remarkable results accomplished in the treatment of angiomata and endotheliomata. In keloid and certain other conditions, radium seems to exert a decided specific effect. In malignant conditions, in addition to a destruction and absorption of the neoplastic elements, there results a proliferation of the connective tissue, and obliteration of the vessel by a swelling of the intima, thereby diminishing the nutrition of the growth. There is probably a certain degree of immunity produced by the absorption of the living tumor cells in the body.

Superficial Epithelioma.—The results obtained from the treatment of nearly 100 cases of superficial epithelioma have been most gratifying. While epithelioma of the face, lips, and eyelids constitute the majority of these cases, they have been quite generally distributed over the surface of the body.

Of three cases, all quite extensive, involving the vulva, one was markedly improved, one is well, and one woman, 84 years of age, died from extension involving the bladder and adjacent tissues. Three cases involving the penis, and one the male urethra, are apparently well.

Sixteen cases of epithelioma involving the lip have been treated, 3 recurrent after surgical removal. More than 60 per cent. of these cases had previously had *x*-ray, violet-ray, paste, or other treatment, without results. In 4 cases, the glands were enlarged, and in 12 were apparently not involved. All of these cases, excepting two, are apparently well, and local treatment over the glands or within the glands has proven effective in de-

*Read before the fifty-eighth regular semiannual meeting of the Southern California Medical Society, at San Diego, May, 1918.

stroying the glandular involvement. The time elapsed since treatment varies from a few months to two years. The cosmetic effect in these cases is truly remarkable. In the majority, it would now be impossible to determine, by any disfigurement present, the original location of the involvement.

The result of the treatment of epithelioma involving the eyelids is equally pleasing, and, of course, more favorable because of the absence of glandular metastasis. Even though extensive involvement is present, cure is effected in practically all cases, with little or no disfigurement, other than the loss of eyelashes on the lid involved. The cornea is apparently very resistant to the rays, and no injury to the eye has resulted from treatment of these cases.

Epitheliomata involving the skin of the face and body yield most satisfactorily, and in only a few cases where extensive and deep involvement is present, usually in older persons, are satisfactory results not obtained. Of nearly 50 of these cases treated, all are apparently well, excepting 4, which were improved. I have seen a number of cases in which marked disfigurement and accentuation of the growth have resulted from the use of pastes; especially is this true if located near the eyes, nose, or lips. In 2 cases, the eye was severely injured from the use of the *x*-ray. I have not seen a recurrence in any case that was once apparently cured following the application of radium. It is generally accepted among men who have had an opportunity to observe the proper application of radium in these cases that it affords the most effective treatent of superficial epitheliomata.

Skin Diseases.—Several skin conditions in which I have received most excellent results with radium therapy are as follows: I have treated 5 cases of lupus, all of which had received previous treatment with various other agents, including the *x*-ray, violet-ray, carbon dioxide snow, drugs, etc.; one case had previously resulted in considerable destruction of the nose; and in one the eyelid was involved. These cases responded promptly and permanently, with an improvement in the preexisting disfigurement.

Pigmented moles may be favorably influenced, although considerable treatment is necessary. Two of those treated covered a considerable area and one had apparently undergone malignant degeneration.

In no condition are more pleasing results obtained than in the treatment of vascular nævi, angiomata, and port wine stains. These conditions are a congenital new growth and hypertrophy of the vascular tissues of the corium and subcutaneous tissues. Because of the susceptibility of endothelial cells to the Beta rays of radium, radium acts almost as a specific. Port wine stains require great patience and most careful technique in their treatment. Three cases, two of which extended through the eyebrows, have been caused to entirely disappear without disfigurement or loss of the eyebrows, and one has been so markedly improved as to render the remaining discoloration negligible, although greater improvement would have been effected by further treatment. Five cases of angiomata, one involving the nasal septum and upper lip, one involving the skin over the nose, one on the neck, one producing marked discoloration and swelling of the mucous membrane of the upper lip, and one producing a tumor about 4 cm. in diameter at the end of the tongue, have all been markedly improved or caused to entirely disappear. The application of radium in vascular nævi is without pain or subsequent inconvenience and is unquestionably more effective than any other method of treatment in these cases.

Verrucæ of various types respond most favorably to radium, although in the majority of cases less expensive methods will prove effective. In those verrucæ, or warts, involving the eyelids, palm of the hand, sole of the foot, or where disfigurement or loss of function might result, radium, which produces little or no scar, is most effective. Radium, apparently, exerts a specific effect upon keloid tissue. Marked improvement has resulted in a number of cases treated. I discovered accidentally, in treating lesions where scar had resulted from previous surgical procedure, that the scar was caused to become less marked, softer, and more pliable; and I have since employed radium with splendid results in the treatment of several scars which caused marked disfigurement or interference of function.

In two cases of acne rosacea involving the nose, the hyperemia and hypertrophy were markedly decreased and the acnelike lesions destroyed, resulting in the nose resuming practically its normal appearance. Several cases of seborrheic eczema, that had resisted other forms of treatment, have been most favorably influenced.

I have treated several cases of superfluous hair on the face. Great care, however, is essential in order to give the dose necessary to destroy the hair follicles, and at the same time cause no scar or discoloration of the skin.

One case of blastomycosis, previously reported, which involved the entire dorsal surface of the hand and wrist, and which had resisted other treatment, was promptly cured with radium.

Urethral caruncles, because of the vascularity of the growths, are quite susceptible to radium, and of 3 cases treated, 2 are apparently well and one markedly improved.

Goiter.—The hypervascular condition of exophthalmic or thyro-toxic goiter renders it susceptible to radium. One case, with a neck measurement increased from a normal 13 inches to 15½ inches, was reduced to 14¼ inches, with complete relief of toxic symptoms. Two cases, in young women with comparatively small enlargements, one involving the isthmus, the other the right lateral lobe, but with some pressure and marked toxic symptoms, were caused to disappear entirely and the toxic symptoms were completely relieved. Colloid or cystic goiter is not, in my opinion, appropriate for radium therapy.

Tuberculous Adenitis.—Tuberculous glands are favorably influenced in a high percentage of cases and the radium may be advantageously employed where marked scarring or possible injury to important nerves or vessels would result from surgical removal. There is less tendency to recurrence and extension of the infection to adjacent glands. One case, in which the parotid gland was involved, after unsuccessful surgical treatment, is now well, nearly 2 years after treatment with radium.

Several cases of tuberculous sinus have responded favorably to radium. One case, in which a sinus 2½ inches in length, resisting other treatment, persisted for several months after resection of the knee joint, was completely healed 2 weeks after the application of radium, and is now well, 2 years after treatment.

I have also used radium in one fecal fistula following appendectomy, with prompt and permanent cure, and with splendid results stimulating healing of chronic and slowly healing wounds.

Five cases of vernal conjunctivitis, 2 very advanced, have been treated, with apparent cures in 3 cases. The other two cases, markedly improved, are still under observation, and may be benefited by additional treatment.

One rather advanced case of chronic ulceration of the septum, which had resisted other treatment, was promptly and permanently cured after several applications of radium.

Leukuplakia, rather uncommon, but extremely resistant to the usual treatment, is favorably influenced by radium, and because of the frequency with which it undergoes malignant degeneration, should receive prompt and effective treatment. I have seen but two cases unassociated with malignant changes, both of which were apparently cured after persistent treatment.

Sarcoma.—I have treated 38 cases of sarcoma, representing nearly all types and variety of location. A detailed report of these cases will be made at another time. The majority of these cases, because of their location, or the character of involvement, were inoperable, or had recurred following surgical procedure. Of these cases, 5 are still under treatment; 10 have been markedly improved; 6 are dead; 17 are apparently well.

Endotheliomata, as a class, are especially susceptible to radium. One case, involving the septum, in a girl nine years of age, is apparently well 8 months after treatment; another, involving the inferior maxilla and overlying mucus membrane, is well nearly 2 years after treatment; a third, involving the mouth, is apparently well more than one year after treatment; and a fourth, in the deltoid region, recurrent after 3 previous surgical procedures, has apparently responded promptly to treatment; in this case, the radium tubes, through punctured incisions, were placed within the tumor substance for the desired interval, resulting in a total disappearance of the tumor in one week's time.

Lymphosarcoma rapidly becomes general after attempted operative removal and is rarely amenable to surgery. When localized, this condition responds favorably to radium in a high percentage of cases. I have treated 3 cases, when after attempted surgical procedures, the condition had become general and all groups of superficial lymphatics were palpable; 2 cases were markedly improved, one of which also received Coley's fluid; the third received local application of radium, and Coley's fluid, and is apparently free from all involvement more than 6 months after treatment.

Glioma Retinæ.—Three cases of recurrent glioma retinæ, previously reported, have been treated; 2 are well, one and two years after treatment; the third, although the orbital recurrence was caused to disappear, has extensive glandular involvement. Recurrent malignant growths involving the orbit are much more successfully treated with radium than by extirpation, yielding a higher percentage of cures with much better cosmetic effect. I have used radium in 2 cases after enucleation of the eye for intraocular malignancy without a recurrence, and I believe that radium should be used as a routine prophylactic treatment in these cases.

Carcinoma.—More than 50 cases of carcinoma, not including superficial epitheliomata, nor uterine cancer, have been treated. A consideration of these cases will form the basis for a later report, as time will not permit of a detailed discussion here. Practically all of these were advanced and inoperable, or recurrent cases. I am confident, from the results obtained, that much more favorable results would be accomplished in earlier cases with less extensive involvement. A large percentage had received, without benefit, *x*-ray, cautery, caustics, serums and various other treatments. The palliative effect in a large number of these cases was truly remarkable.

The 54 cases treated involved a number of different organs and parts, and represented a considerable variation in the type and character of involvement. Of these, 10 are still under observation and treatment, 15 have been markedly improved, 10 are dead, and 19 are apparently well. The time elapsed since treatment in those apparently well, or free from all evidence of involvement, is from 6 months to 2 years.

Recurrent carcinoma of the breast, if not too advanced, can be markedly benefited in a large percentage of cases. Three of nine cases treated are apparently well. In one other, the breast involvement entirely disappeared, although the patient died later from metastasis in the stomach.

Carcinoma of the bladder or prostate in men yields excellent palliative results and a number of cases treated are apparently well. Carcinoma of the bladder in women has responded very favorably, even though extensively involved. The condition usually involves the base of the bladder and in addition to the radium placed directly within the bladder, large doses of radium may be applied within the vagina, raying through the anterior vaginal wall, with little, or no, discomfort to the patient.

Rectal carcinoma is very difficult to treat, requiring considerable patience and time. In conditions involving the lower segment, results are apparently more satisfactory than from surgery or other treatment.

Carcinoma involving the mouth and buccal mucus membranes have, with careful technique, responded very satisfactorily.

My experience with five cases of carcinoma of the tongue has been most gratifying. All were early cases, excepting one, which is still under treatment and has received marked improvement. Diagnosis was confirmed by section in 4 cases. In one case, in which section was not taken, the tongue condition cleared up entirely, but six months later the patient evidenced a metastasis in the stomach. The other three cases are apparently well after intervals of from five to twenty months.

Glandular carcinoma, both primary and metastatic, has responded most satisfactorily. A num-

ber of cases, which rapidly increased under intensive *x*-ray treatment, have responded promptly to radium and remain apparently well.

Carcinoma Uteri.—While by no means accomplishing all that we might desire in the treatment of uterine cancer, radium has proven far superior to any other therapeutic measure in the treatment of inoperable and recurrent cases. More than 50 of these cases, that I have treated, formed the basis for a recent paper. Hemorrhage and the odorous discharge are promptly arrested, pain is relieved, and life is prolonged in more than 80 per cent. of the cases treated. The results obtained in 31 consecutive cases, treated previous to the past 8 months, are shown in the following table:—

Carcinoma Uteri.

Type of Case.	No. Treated.	Dead.	Improved.	Clinically Well.		Months Elapsed Since Treatment.						
				No.	%	8	9	10	11	13	17	22
Operable.....	1	0	0	1	100	..	..	..	..	..	..	1
Inoperable....	10	2	3	5	50	1	2	..	1	1	1	..
Recurrent....	20	9	5	6	30	2	1	1	..	1	..	1
Total.....	31	11	8	12	38 7	3	3	1	1	2	1	2

Uterine Bleeding.—Uterine bleeding, due to metropathies, disturbed ovarian function, chronic endometritis, and uterine myomata, are most favorably affected by radium. Not only is the hemorrhage promptly arrested, but tumors, when present, are caused to diminish rapidly in size, and in many instances completely disappear. The application of radium within the uterine canal is comparatively simple, although strict asepsis must be maintained and considerable judgment is necessary in determining dosage. Results are due not alone to the structural changes produced in the ovary, for radium seems to exert, in these cases, a decided specific effect in addition to producing obliteration of the blood vessels and structural changes in the endometrium. I have treated one case in which profuse uterine bleeding occurred after double oophorectomy and promptly arrested the hemorrhage, and relieved 2 cases of metrorrhagia and menorrhagia in young women, conserving the normal menstruation. Results in these three cases were certainly not due to changes produced by radium in the ovaries. Six other cases of uterine hemorrhage, unassociated with palpable tumors, have been treated with perfect results, and 10 cases of myomata uteri, with the uterus varying in size from that of a two to that of a six months' pregnancy, have been treated with marked reduction or total disappearance, of the tumor and relief of symptoms in all cases. Certainly, radium therapy is preferable to a dangerous and mutilating operation, and is free from all post-operative complications or sequelæ. Menopausal symptoms are absent or mild in the majority of cases treated. The cry raised by many surgeons, that malignant changes may be overlooked, is of little importance, inasmuch as a careful review of the literature does not reveal a single case reported in which malignant changes have followed the use of radium in the treatment of uterine myomata.

Leukemia.—I have treated 3 cases of splenomyelogenous leukemia, all of which were very advanced cases. One woman, in whom the spleen occupied more than half of the abdominal cavity, now shows a practically normal blood count, is free from symptoms, and the spleen is reduced to about 3 inches below the costal margin. Another case, in a young man, was promptly relieved and remained apparently well for nearly six months, when, due perhaps to adverse living conditions and overwork, there developed a recurrence, ultimately ending in his death. In the third case, there resulted a prompt improvement in the blood picture, marked reduction in the size of the spleen, with relief of symptoms. This patient stopped treatment early, and under heavy work and worry there resulted a sudden recurrence, which has since yielded to further treatment. In addition to radium therapy over a long period of time, rest, freedom from worry, and proper general care are essential.

I have used radium as a prophylactic following the surgical treatment of malignancy in a large and varied group of cases, but, while the results are apparently very encouraging, considerable time must elapse before we can determine how much benefit actually resulted from the use of radium in these cases. Recurrences are apparently less frequent, and, theoretically, prophylactic radiation with radium is a conservative measure.

JUVENILE PERIPHERAL GANGRENE IN INFECTIOUS DISEASES.

I.—DIPHTHERIA.

By F. ROBBINS, M.D.,

NEW YORK.

Peripheral gangrene occurring in the course of diphtheria is usually the result of arterial embolism, but has occasionally been observed in the form of Raynaud's symmetrical gangrene, or as the result of septic infection with anerobic germs. The occurrence of a true diphtheritic arteritis, resulting in peripheral gangrene, aside from that following upon arterial embolism derived from the heart, is still a matter of controversy. Bailey produced in rabbits by the intravenous injection of large doses of diphtheria toxin a vascular degeneration involving the entire aorta, the carotids to the base of the skull, the subclavians, and iliacs, and for a varying distance distally, the brachials, femorals, and large abdominal vessels. (*Jour. Exp. Med.*, 25, 1917, p. 109.) In the majority of the cases of diphtheritic peripheral gangrene the arteries of the extremities become obliterated as a result of heart clot.

This serious complication is fortunately rare, but a search of the literature has yielded twenty-five positive cases. A tabulation of these cases and a brief consideration of the subject appear to be desirable, for the reason that remote complications of this treacherous disease, diphtheria, are observed now with greater frequency than in the past, in consequence of the prolonged survival of otherwise doomed patients, by the use of anti-diphtheritic serum. The lowered blood pressure, sluggish circulation, myocarditic and endocarditic changes, all combine to form heart clots, which, when detached and mobilized, may become the starting

point of emboli, lodging in the arteries of the brain, the lungs, the abdominal viscera, or in the peripheral arteries of the limbs. In a curious case reported by Flesch, in 1898, the patient's death on the sixth day of the disease was due to multiple pulmonary emboli, probably derived from thrombosis of the jugular vein through ulceration of the pharynx. At the autopsy of a boy of six years who had died from diphtheria, d'Espine and Mallet found dilatation and hypertrophy of the heart, with numerous small parietal thrombi in the ventricles and auricles. A thrombus the size of a pigeon's egg occupied the mitral ostium and the upper portion of the left ventricle; the detached pedicle of the thrombus was lodged in the auricle. Multiple emboli were found in the pulmonary arteries.

Complications on the part of the heart, in malignant diphtheria, are usually sufficiently accounted for by the existing lesions of the heart muscle, in the form of diphtheritic myocarditis. As a result of the anatomical changes of the cardiac walls the heart muscle loses its elasticity and becomes distended by the pressure of the circulating blood, the functional insufficiency of the myocardium manifesting itself in the form of dilatation of the heart chambers. The intracardiac circulation is the first to be affected by the stagnating and infected blood, especially in the auricles, where bloody coagula are most apt to form. Aside from the altered composition of the blood through the diphtheritic poison, coagulation of the blood is more rapid in children than in adults (Howells). Changes of the endocardium, more particularly in the form of diphtheritic endocarditis of the cardiac apex, may also play an important part in the production of arterial thrombosis and embolism.

The question if thrombosis can be caused in a blood vessel, in the absence of other causative factors, through infectious processes in the vicinity of the vascular wall, was recently investigated by Nagoya in animal experimentation. He endeavored to ascertain if the pathogenic bacteria are directly responsible for the thrombosis, and to determine the part played by the retardation of the blood stream and the lesion of the vascular wall respectively. A loopful of fresh bacterial culture (staphylococci, streptococci, pneumococci) was deposited directly on the walls of the carefully exposed blood vessels, and after definite intervals a vascular segment of about 0.5 cm. in length was excised and examined. Thrombosis, it was found, could be produced through infection alone, without other causative factors. As a rule, the resulting thrombi are composed of blood platelets, the blood plate thrombus serving as a foundation or nucleus for further thrombi. No direct influence is exerted by the bacteria in thromboses of this type. The most important element in the production of the thrombosis is the lesion of the vascular wall, the retardation of the blood current acting as a secondary and auxiliary factor. (*Virchow's Archiv*, 216, 1914.)

The occurrence of diphtheria bacilli in the circulating blood is confirmed by the investigations of Rodelius (1913), who was enabled to demonstrate this very rare form of bacteriemia in three of 187 cases (with 196 blood withdrawals and tests). The bacilli may circulate in the blood for days prior to death; this diphtheritic bacteriemia may be temporary, and is not necessarily fatal. References in the literature to the condition of the peripheral vascular system in diphtheria comprise mention of primary diffuse endoarteritic changes of the intima, interruption in the continuity of the internal elastica, edema of the vascular wall, and lesions of the small arterioles.

Cardiovascular lesions, due to serotherapy, have been suspected as possibly responsible for post diphtheritic deaths from heart failure or embolism, but the anatomical proof of this assertion has not been furnished. Nevertheless, it must be kept in mind that the heart and the blood vessels play a decisive part in the struggle for supremacy between the body and the diphtheritic toxin. The strictest and most persistent control of the general circulation is accordingly imperative. The danger of circulatory failure threatens life and limb a long time after the subsidence of the diphtheritic attack itself.

The cause of acute cardiovascular failure, in malignant or hypertoxic cases of diphtheria, has been referred by numerous investigators to intoxication and exhaustion of the secretory cellular elements of the suprarenal glands, imperfect function of the chromaffin portion, loss of the detoxicating effect of the organ; briefly, suprarenal insufficiency and a resulting lack of suprarenin (adrenalin) in the blood. If the patient survives this stage, these suprarenal changes after a few days cease to progress, and may even undergo a certain amount of retrogression. Clinically, endocrinic suprarenal medication is found to be most efficient in the first days after the onset of the disease. The administration of the glandular extract promptly improves the circulation and raises the blood pressure. The dangerous lowering of the blood pressure in diphtheria has been explained either as a sequel of toxic myocarditis or as the expression of vasomotor paralysis.

Taddei, in a contribution published in an Italian periodical (*Rivista di Clin. Pediat.*, II, 1904, p. 907), studied the arterial pressure in diphtheria and pointed out that its changes are directly proportionate to the gravity of the intoxication. The behavior of the arterial pressure is especially significant from the prognostic viewpoint, in regard to complications on the part of the myocardium, for it indicates the degree of functional involvement of the heart. Ten years later two other Italian investigators, Mattirolo and Gamma (1914), found in animal experimentation on rabbits that intravenous injection of extract of the posterior lobe of the hypophysis caused primarily a brief rise of blood pressure, with slowing and strengthening of the heart action; this was followed by a period of lowered blood pressure, and finally by a repeated and prolonged rise of blood pressure, with improved action of the heart.

The strong blood pressure-raising effect of pituitrin in diphtheritic hypotonia of the vascular system, as pointed out by Creutzfeld and Koch (1913), suggests a part played by the cerebral hypophysis in this lowering of the blood pressure. They were enabled to show that this organ, more particularly its intermediate portion, is seriously affected in diphtheria, aside from the grave and better-known lesions of the suprarenal parenchyma. In view of the dependence of the blood pressure upon the secretion of these two endocrinic glands, in form

of pituitrin and adrenalin, it is readily understood that the loss of normal function of these organs may so essentially diminish the tension needed for the survival of the patient as to render death inevitable. In the experience of Willebrand, in twenty severe cases of diphtheria, the hypotonia of the vascular system was so favorably affected by the injection of pituitrin as to result in a considerable rise of blood pressure. Pituitrin is advocated as a remedy in diphtheritic lowering of the blood pressure, by Klotz, on the basis of experiments which showed the production of a single long-continued rise of blood pressure, precisely in toxic hypotonias. He claims that a uniform high blood pressure may be maintained by means of judicious administration of pituitrin, while there is no reason to fear an injurious effect of the prolonged hypophyseal medication.

As the most rational method of treatment for diphtheritic circulatory disturbances, Creutzfeld and Koch recommend a combined treatment with pituitrin and adrenalin. This modern therapy represents a specific mode of treatment in diphtheritic paralysis of the heart and vascular system. According to these observers, in patients who die in the early stage of diphtheria from failure of the circulatory apparatus, the vascular system presents pathological phenomena before changes of the heart are clinically demonstrable, and in other cases the cardiac changes are not sufficient to account for the grave atony of the vascular system. Death in the worst toxic cases of diphtheria is preceded by a well-marked fall of blood pressure. Hypophysis extract in the form of pituitrin was employed by Willebrand in twenty cases of heart failure, with diminished blood pressure, in diphtheria, with excellent results in eighteen cases. In only two patients the remedy failed to produce the desired effect; this is noteworthy in view of the missing response to pituitrin in certain cases where it is used as an adjuvant to childbirth (Stein). Willebrand accordingly recommends the employment of hypophysis extract as a prophylactic agent, in diphtheria, in addition to large doses of serum and the ordinary heart stimulants.

The following list of deaths and mutilations of children, due to gangrene of the extremities after diphtheria, carries an urgent appeal for help in the form of renewed assiduous attempts to influence the blood pressure and to improve the peripheral circulation. This list of reported cases of peripheral diphtheritic gangrene is given in inverse chronological order.

Case I.—*Gunson, E. B.* Gangrene of the Leg, following Diphtheria. (*British Jrl. of Children's Diseases*, XIII, 1916, p. 237.)

The patient, a boy of six years, was admitted to the Grove Fever Hospital with severe faucial diphtheria on the fourth day of the disease; he was given 20,000 units of antitoxin on admission and again on the following day. The pulse became very irregular on the seventeenth day; there was marked pallor of the face, but the extremities remained warm. At 6 P.M. the patient cried out with pain in the right leg, referred to the popliteal space. The following day, the limb was discolored, warm but of lower temperature than the left; there was some cyanosis of the skin immediately below the knee; at 4 P.M. a ring of edema appeared about 1½ in. below the knee at the site of discoloration and became more definite in the course of the next few days. The circulation in the superficial veins was maintained. On the twenty-second day, dry gangrene of the right small toe developed; during the day the outer aspect of the foot became black, and the skin over the right knee was deeply discolored. On the thirtieth day, the whole of the right leg below the level of the knee-joint was in a state of dry gangrene. No extension of the gangrenous area occurred during the next fortnight, while the patient's general condition slowly improved, and a well-marked line of demarcation developed. On the fortieth day sloughing of the skin commenced at the upper limit of demarcation; a slight separation of the skin followed, and septic ulceration occurred. On the seventy-first day he was transferred to the Evelina Hospital and three days later an operation was performed in form of amputation of the limb about the middle of the thigh. One year later, the amputation stump was firm and the patient suffered from no pain or discomfort in the limb. On examination the popliteal artery was found to be completely occluded by a thrombus extending for a distance of 2 in. above the bifurcation of the artery. The embolus is referred by the observer to thrombus formation within the left ventricle, the result of the considerable degree of cardiac dilatation and enfeeblement which followed upon the onset of a marked arrhythmia.

Case II.—*Veau et Weber.* Gangrène du pied dans la diphthérie. (*Annales de Méd. et Chir. Infant.* XVIII, No. 10, 1914—p. 335). This is the same case as Bailly's personal report in Thèse de Paris 1913.

The patient, a girl aged 5½ years, suffering from extremely severe diphtheria treated with serum injections was attacked during the night of the nineteenth day of the disease by violent abdominal pains; at this time, the two feet and legs became suddenly cold and cyanotic up to the knee. In the course of the next day, the arrest of circulation in both lower extremities plainly manifested itself in form of pallor, coldness, loss of sensation and flaccidity. No femoral pulsation was perceptible on either side. The extremities remained in the same condition during the next day, although the femoral pulsation gradually returned, first on the left side, the left foot becoming warm and of a better color. This improvement continued, but the state of the right extremity remained unaltered and the general condition was very unsatisfactory. Later on, the dorsum of the right foot became edematous, and the surroundings of the big toe (the nail of which was brown and discolored) were reddened. From the twenty-fifth day, the plantar surface of the toes appeared dry, hard, and darkened; the entire sole and back of the foot presented a cyanotic color, and reddish purple patches were noted on the lower portion of the leg. In the course of the next day or so, apparently superficial gangrene began to extend from the anterior portion of the sole to the heel, and the toes became entirely necrotic. The general condition slowly improved, and the local condition of the right leg was slightly relieved by means of hot air treatment. Although large vesicles had made their appearance on the foot and lower leg, these subsided again, together with the edema, and the leg gradually resumed its normal aspect, the gangrene remaining restricted to the toes and the superficial tissues of the anterior half of the sole of the foot. Surgical intervention was postponed, in this typical case of dry gangrene with a distinct line of demarcation, because the general and local condition were excellent, and because the new skin could be seen progressively invading the gangrenous area. When there was no further progress, amputation was decided upon and performed four months after the onset of the diphtheria. The foot was removed, practically without hemorrhage, at the level of Chopart's articulation. The patient made a good recovery, has a serviceable stump allowing useful flexion and extension movements, and walks without limping with an artificial jointed foot.

Case III.—*Aviragnet, Blechmann, Huber.* (Un cas de gangrène embolique d'un membre consécutif à une angine diphthéritique maligne. (*Archiv. de Méd. des Enfants*, Vol. XV, 1912, p. 263.)

The following case is undoubtedly one of embolic peripheral gangrene, complicating diphtheria, although the anatomical demonstration is lacking. The patient, a boy of 13 years, a fortnight after the onset of a bad

attack of diphtheria, treated by serum injections, suddenly complained of severe colicky pains in the lower abdomen, accompanied by tingling sensations in the legs, especially the right. Inspection proved negative, but on gentle rubbing of the thighs with alcohol, purplish spots made their appearance on the upper two thirds, the entire limb lower down becoming cold, bloodless, and insensible to pain. Pulsation was entirely lost in the external iliac, the femoral, the popliteal, and the dorsalis pedis arteries. On the next day, the left leg felt warmer, and the arterial pulsations had returned, but the right leg below the knee was cold, covered with dark spots, and absolutely anesthetic. Arterial pulsation was lost below the femoral. Under progressive asphyxiation and cyanosis of the face as well as the extremities, the patient died on the next following day. In the opinion of the observers, the embolism probably originated in the left ventricle and definitely lodged in a large arterial trunk of the right lower extremity, after having temporarily elicited the signs of arrested circulation at the level of the abdominal aorta.

Case IV.—*Ransome, A. S., Corner, E. M.* Gangrene of limb during convalescence from Diphtheria. (The Lancet, 1, 1911, p. 94.)

On the seventeenth day of a severe attack of diphtheria, treated with antitoxin, in a boy aged six years, very acute cramplike pains suddenly appeared in the right leg, and during the next few days, the right foot and leg became discolored in patches, the discoloration of the leg, later on subsiding to below the juncture of the middle and lower third of the leg and foot. The patches over the foot and lower part of the leg gradually coalesced so that the foot was one even purple color. The leg was painful and was kept flexed. A blister appeared on the ankle, and the toes became black, dry, and shrivelled. One month after the onset of gangrenous symptoms, a well-marked line of demarcation had formed at the junction of the lower and middle third of the leg, and a fortnight later (on the forty-sixth day of the embolism, and the sixty-first day of the illness) the leg was amputated just below the knee. The child made an uneventful recovery. According to the findings at the time of operation, as well as clinical observation, the embolus was situated above the bifurcation of the popliteal artery, possibly in the femoral artery at the bifurcation of the superficial femoral.

Case V.—*Heubner, C.* Herzthromben und sekundâre Embolien. Lehrbuch der Kinderheilkunde, Vol. 1, 1911, p. 497.

An attack of diphtheria, in a boy aged eight years, was followed by distinctly palpable obliteration of the brachial artery in its highest portion in the axilla. Although the entire forearm at first appeared to be necrotic and doomed, recovery ensued with the loss of a few digital phalanges and stiffened finger-joints.

(Heubner briefly mentions three other cases of embolism of peripheral arteries, with gangrene of the affected extremity, about the end of the third week, in children suffering from diphtheria complicated by measles.)

Case VI.—*Kramer, H.* Gangrene of leg following diphtheria. (*British Med. Jrl.* II, 1911, p. 505.)

The patient, a girl of eleven years, during convalescence from diphtheria (treated with antitoxin injections), was attacked by progressive and extensive gangrene, beginning with small sores on both feet and one leg. When the condition had advanced to "gangrene complete to the level of the tubercle of the tibia, with a patch of skin over the patella gangrenous," operation was advised, and the limb was amputated well above the knee. The child made a good recovery, somewhat delayed by an attack of measles on the ninth day after operation.

Case VII.—*Rolleston, J. O.* Gangrene of leg following diphtheria. (*British Jrl. of Children's Diseases*, Vol. VII, 1910, p. 529.)

In a case of diphtheria concerning a boy of 13 years (who received no antitoxin) the right leg from the knee downwards became cold, pale and anaesthetic on the day of admission to the Grove Hospital for diphtheria, on the seventeenth day of the disease. The circulation was reestablished in about four hours. On the twenty-first day, both legs became cold, discolored, and numb, pulsation was feeble in the posterior tibial and dorsalis pedis arteries; on the next day, the discoloration of the legs had disappeared. On the thirtieth day, sudden pain was felt in the left leg, followed by discoloration; there was marked tenderness in the popliteal space, where the pulsation of the popliteal artery could not be felt. The femoral pulse was present in Scarpa's triangle. Gangrene rapidly developed in the left foot and leg, the gangrenous area on the eighty-second day of the disease involving the whole of the left foot, and extending posteriorly to 7 inches below the popliteal space. Six days later, on the eighty-eighth day of the disease, amputation was performed at the knee-joint, and an organizing clot was found in the popliteal artery. The patient made an uneventful recovery. Earlier intervention was considered inadvisable on account of his general weakness and the condition of the heart.

Case VIII.—*Bendix, B.* Diphtheritische Extremitäten-gangrän. (Lehrbuch der Kinderheilkunde, VI edition, 1910, p. 528.)

Observation, in 1905, on a boy aged ten years, in whom a severe attack of diphtheria was followed by extensive gangrene of the index and middle finger of the right hand. Surgical treatment led to uneventful recovery.

Case IX.—*Escherich, Th.* Hirnembolie im Verlaufe der postdiphtheritischen Herzschwäche; Embolische Prozesse bei postdiphtheritischer Herzschwäche. (*Wiener Med. Wochenschrift*, 57, 1907, p. 474.)

The patient, a boy two years of age, was admitted five days after the onset of diphtheria angina in a state of somnolence, with right sided hemiplegia and facial paresis. Convulsions supervened on the next following day; one day later the paralysis remained unchanged; both legs were cold to the touch and showed livid discolored patches, the rest of the skin being of a cadaverous pallor. The child became unconscious, but the livid discoloration of the legs could be seen extending up to the lower abdominal region. The legs were cold and pulsation had disappeared in the dorsalis pedis as well as the popliteal artery. Below Poupart's ligament, it was barely perceptible on the left and just demonstrable on the right side. No difference could be noted in the radial arteries. Death occurred that night with progressive cyanosis and frequency of pulse. The autopsy showed in addition to ventricular thrombosis, embolism of the left middle cerebral artery, and embolism of the left iliac artery exactly at the bifurcation, with a fresh propagated red thrombus; embolus of the right femoral artery below Poupart's ligament, also with a propagated fresh red thrombus; incipient gangrene of the lower extremities.

Case X.—*Garlipp's* Case. Embolie der Arteria Brachialis dextera nach Diphtherie mit Ausgang in Heilung. (Charite—Annalen Vol. XXX, 1906, p. 145.)

Patient, boy aged 2¾ years; attack of diphtheria, treated with antitoxin. In the third week, after convalescence was established, the child suddenly complained of severe pain in the right hand, which looked like a "dead" hand; the right arm was cold, white, stiff and paralyzed. On the next day, the hand became blue and discolored, the finger-tips were of a dark blue color, and the hand was contracted into a fist. Gradually the hand and forearm became swollen and edematous, the bluish discoloration involving nearly the entire hand and a portion of the forearm. Five days later the patient was admitted to the Charite' Hospital. The right hand was edematous and discolored, with localized black patches, the ungual phalanges of the index and fourth finger were completely mummified. The edema and cutaneous discoloration extended to the forearm reaching on the ulnar side nearly midway, two fingers width above the wrist on the radial side. The dorsum of the hand presented a gangrenous cutaneous area the size of a penny over the second and third metacarpal bones. An induration could be felt in the brachial artery about 3cm. below the border of the pectoralis major; a weak pulsation was palpable above this thickening whereas pulsation was not perceptible above this point in the brachial, ulnar, and radial arteries. Under expectant treatment, the condition very gradually improved, and at the time of discharge, about twelve

weeks later, pulsation was again palpable in the entire course of the brachial artery, except the indurated segment, and also in the radial, still later also in the ulnar. The skin of the terminal phalanges of the fingers except the thumb was necrotic, but the skin of the little finger subsequently became regenerated. The terminal phalanx of the index finger was shed as a whole, and also on the dorsal aspect of the middle phalanx the soft parts became necrotic, so as to expose part of the bone. The tip of the terminal phalanx of the middle finger and the terminal phalanx of the fourth became necrotic and dropped off. The explanation of the relatively favorable outcome, after the at first very alarming symptoms of arterial embolism, must be referred to the prompt establishment of an adequate collateral blood-supply. Ultimately the necrosis was restricted to the terminal phalanges of the index, middle and fourth fingers, as well as a portion of the skin of the back of the hand and forearm.

Case XI.—*Marfan's* Case. Thrombose cardiaque et embolie de l'aorte abdominale après une angine diphthéritique maligne. (Leçons Cliniques sur la Diphthèrie, Paris, 1905, p. 50.)

Cardiac thrombosis and embolism of the abdominal aorta following malignant diphtheria, treated with anti-diphtheritic serum. Patient, boy aged six years, was suddenly attacked on thirteenth day of disease, by severe abdominal pain, slightly above the level of the umbilicus. The extremities were cold, the radial pulse was weak but could still be counted. Next morning pulsation was imperceptible, the heart-beat was very weak, the extremities remained cold, and the patient died. The autopsy showed the aortic lumen directly below the origin of the coliac axis to be obliterated by a soft non-adherent clot which was prolonged into the two common iliacs, stopping on the right side at the bifurcation of the common iliacs, while in the left side it penetrated into the external iliac and the hypogastric artery. Peripheral gangrene here was evidently only a question of time.

Case XII.—*Auché.* Embolic des deux artères iliaques primitives au cours de la diphthérie. (*Revue Mens. des Maladies des Enfants*, Vol. 22, 1904, p. 326.)

Eighteen days after the onset of diphtheria angina, treated with serum injections, the patient, a boy of 4½ years, was attacked by pains in the legs, suggesting embolic obliteration of the main arteries of both lower limbs. On the right side, the circulation was restored on the next day, and the limb resumed its normal appearance, whereas on the left side, signs were noted indicating the absence of an arterial blood-supply to the foot and leg. The time was too short for the evolution of gangrene, as the patient died two days after the onset of the embolic complications from diphtheritic involvement of the heart and kidneys. The autopsy showed the presence of arterial embolism, apex thrombosis of both ventricles. Two thrombi were found, one 5 cm. in length occupying both the termination of the left external iliac artery and the origin of the left femoral artery; the other 2½ cm. long, obliterating the upper portion of the femoral artery.

Case XIII.—*Breton's* Case. Paralysie méta-diphthéritique due à des embolics multiples. (Bulletins de la Soc. de Péd. de Paris, IV, 1902, p. 244.)

Patient, girl aged three years; moderately severe attack of diphtheritic angina, verified by bacteriological findings ten days later. After apparent recovery, infectious phenomena supervened, first in the digestive apparatus, then in the heart. Endocarditis was followed by multiple embolism causing left sided hemiplegia and incipient gangrene of the right foot, with necrotic patches in various areas of the right lower extremity. Improvement after injections of antidiphtheritic serum, which in its turn gave rise to a series of toxic manifestations. The child made a good recovery also from the post diphtheritic paralysis resulting from the left hemiplegia.

Case XIV.—*Goebel.* Spontane Gangrän bei einem Kinde auf Grunde einer Gefässerkeankung. (*Deutsches Arch. f. Klin. Med.*, Vol. 63, 1899, p. 184.)

In this case an embolic origin of the thrombus could be excluded in view of the absence of primary thrombosis or infection in other organs. The thrombus was autochthonous and originated in the vascular system. The patient, a boy seventeen months of age, with a history of repeated attacks of tracheal catarrh, with fever and cough, entered the hospital a fortnight after a moderately severe attack of tonsillar angina accompanied by a rash over the entire body, which disappeared after three days. For three weeks past, the child had favored his left leg when attempting to walk, and the limb now took on a "glazed" appearance; it was very cold, slightly swollen, and very soon became entirely discolored, from the toes to the lower half of the leg. Pulsation could be felt in the popliteal space and in the groin. The gangrene rapidly progressed until about two weeks later the entire circumference of the leg was involved and a distinct line of demarcation had formed; within a few days, the necrotic tissue became detached down to the bone. Surgical interference was refused by the parents, and the patient died after another week, under symptoms of sepsis. One day before death, an edematous swelling of the neck suddenly developed, and the tonsils were seen to be reddened and covered with a shiny layer. The autopsy showed necrotic distintegration of both tonsils, and catarrhal pneumonia. The heart was dilated, the myocardium firm and normal, no deposits on the valvular apparatus; no thrombi in the cardiac cavities. A thrombus was found beginning in the abdominal aorta and continued on the left side as far as the bifurcation of the popliteal artery, projecting into the tibialis antica and postica; on the right side, it extended but slightly beyond the origin of the profundafemoris. All afferent vessels in the thrombotic area were blocked.

Case XV.—*Munn, W. P.* Embolus following diphtheria; gangrene of left leg; amputation; recovery. (*Pittsburgh Med. Review*, VIII, 1894, p. 73.)

Patient, boy age nine years; nasopharyngeal diphtheria of five weeks' standing; attack marked by precordial pain, collapse, and unconsciousness, followed three hours later by coldness and progressive discoloration of the left leg up to the middle third. Although the foot was quite dry and beginning to mummify, amputation was postponed until the line of demarcation had formed, one week later, a little above the middle of the leg. Pulsation was not perceptible in either the left femoral or the popliteal arteries; but was reestablished in the left femoral after the amputation, suggesting a high lodgment of the embolus. Recovery uneventful.

Case XVI.—*Ward, S. M.* Clinical Memorandum. (*Pittsburgh Med. Review*, Vol. VIII, 1894, p. 239.)

Patient, girl age twelve years, on sixth day of diphtheria was suddenly attacked by an intense pain in the left leg, which was cold, and livid in color. The stoppage of the circulation was evidently in the popliteal artery before the anterior tibial is given off. The patient died before the slightest evidence of a line of demarcation was apparent.

Case XVII.—*Rooney, R. F.* Embolism of the popliteal artery following diphtheria. (*Occidental Med. Times*, VII, 1893, p. 188.)

Patient, girl age seven years; severe faucial and nasal diphtheria; during convalescence, was suddenly attacked by intolerable pain in the bowels in the region of the umbilicus, with coldness and numbness of both legs. The left leg from the knee down remained cold, bloodless, and shrunken, and was held tightly flexed on the thigh. Intense pain was complained of in the toes of the affected side. The diagnosis of embolus of the left popliteal artery was made and after waiting three weeks for a line of demarcation to form, the thigh was amputated at the junction of the middle and lower third. Rapid and uneventful recovery followed. The embolus after the amputation was dissected out, in form of a firm whitish plug of fibrin, an inch and a quarter long, from the popliteal at its bifurcation into the anterior and posterior tibials.

Case XVIII.—*Henoch's* Case. Discussion of Leyden's paper on Infectiöse Thrombose. (*Berliner klin. Wochenschrift*, Vol. 27, 1890, p. 481.)

Patient, boy aged eight years, with very severe diphtheria, was attacked by thrombosis of both iliac arteries, the result of cardiac embolism.

Case XIX.—*Rosenthal's* Case. (*Ibid*).

Patient, girl aged two years, with grave diphtheria, promptly terminating in death. Both legs presented a

bluish discoloration and the autopsy showed thrombosis of the common iliac artery.

CASE XX.—*Escolar's* Case. Angina diphtherica, terminada por gangrena; muerte a las 22 horas de su ingreso en el hospital. Autopsia. (*El Siglo Medico*. Madrid, 1886, XIII, p. 488.)

Diphtheritic angina terminating in gangrene; death 22 hours after admission to the hospital. (Inaccessible.) It does not result from the title if the gangrene was *peripheral*.

CASE XXI.—*Poupon's* Case. Embolie de l'artère fémorale dans la convalescence de la diphthérie. (*Le Progrès Médical*, VII, 1883, p. 10.)

Patient, girl seven and a half months old; discharged from hospital, two weeks after tracheotomy for croup; readmitted ten days later with symptoms of pulmonary embolism. Next day, there was pain over the right popliteal space, and in the morning, purplish gangrenous patches were seen over the whole foot. The leg was cold and anaesthetic, the pulsations in the popliteal and even in the femoral artery were imperceptible. The diagnosis was embolism of the popliteal artery. Death on the thirteenth day after readmission. The autopsy showed a brownish clot three centimeters long occupying the whole lumen of the femoral artery, starting from the ring of the great adductor and proceeding to the centre of the popliteal artery.

CASE XXII.—*Bouchut's* Case. Gangrène de la jambe dans la diphthérie par thrombose de l' artère fémorale. (*Paris Méd.* VII, 1882, p. 145.)

Gangrene of the leg in diphtheria, due to thrombosis of the femoral artery.

CASE XXIII.—*Vedder, J.* Gangrene of the leg caused by embolism following diphtheria. (Trans. of Med. Soc. State of New York, 1879, p. 259.)

Patient, boy age eight years; severe attack of nasopharyngeal diphtheria; ten days later, during convalescence, numbness and pain were complained of in the right leg, which was cold, of waxy appearance, and anaesthetic and "dead" from the knee downward. On the next day, the leg was of light mahogany color which gradually grew darker until it was nearly black. The bottom of the foot became quite dark, dry, hard and shrivelled up in a few days. Death on eleventh day after onset of embolism. No autopsy.

CASE XXIV.—*Menzel's* Case. Gangrena della gamba in seguita a difterite delle fauci; amputazione del crure nel terzo superiore. (Resoc. San. degli Ospedali di Trieste, IV, 1878, p. 397.)

Gangrene of leg following upon faucial diphtheria, amputation at upper third of leg. (Inaccessible.)

CASE XXV.—*Moroni's* Case. Gangrena d'un estremità in seguito a difterite. (*Giornale Veneto di Sc. Med.*, Venezia, XXII, 1875, p. 510.)

Gangrene of an extremity as a sequel of diphtheria. (Inaccessible.)

THE THERAPEUTICS OF PHENYLCINCHONINIC ACID.

BY REYNOLD WEBB WILCOX, M.D., D.C.L.

NEW YORK.

PRESIDENT OF THE AMERICAN COLLEGE OF PHYSICIANS.

THIS remedy, first described by Doebner and Gieseke and tested clinically by Nicolaier in 1908, has been before the medical profession as a controlled product since 1910. Its extensive use and the excellent results obtained from its employment led to its incorporation as phenylcinchoninic acid in the ninth edition of the United States Pharmacopœia, which became official September 1, 1916. It would seem to be opportune that a *résumé* of the results of laboratory investigation and clinical observation should be presented at this time in order that an accurate statement may be made as to the value of the remedy.

*Read by title at the American Therapeutic Society at its Nineteenth Annual Meeting at Richmond, Va., on June 8, 1918.

Acidum phenylcinchoninicum, phenylcinchoninic acid, is an organic acid,—2—phenyl—quinoline-4—carboxylic acid, $C_{16}H_{11}O_2N$ or $C_6H_5.C_9H_5N.COOH = 249.10$.

Source.—By warming pyroracemic acid, benzaldehyde, and aniline in an alcoholic solution, followed by filtration and purification.

Characters.—Small colorless needles or a white or yellowish-white microcrystalline powder, odorless or having a slight odor resembling benzoic acid, and a bitter taste. It is permanent in the air.

Solubility.—Insoluble in cold water; slightly soluble in cold alcohol, hot water, or ether; soluble in alkalies and, upon heating, in acids; readily soluble in hot alcohol.

Dose.—0.5 gm. = 500 milligrams (8 grains).

Action of phenylcinchoninic acid.—This manifests itself largely upon the kidneys, chiefly stimulating their circulatory cells, generally increasing the flow of urine but not the amount of elimination of the purin bodies, sulphur, or phosphoric acid. It markedly augments the elimination of uric acid in man, in most instances even when upon a purin-free diet. This action is stronger and more promptly manifested than after the use of salicylic acid. Inasmuch as there is no increase in the number of leucocytes, which occurs after the exhibition of the latter remedy, this increase of uric acid elimination cannot be due to their destruction, and, further, this increase is noted not only when the individual is subsisting upon a mixed but equally as well when he is ingesting a purin-free diet. One observer, investigating its effect upon the endogenous uric acid excretion of healthy individuals, found that after a week of purin-free diet 30 grains of phenylcinchoninic acid administered for one day increased the uric acid excretion by more than 3 grains. During the period following the administration of the drug the amount of uric acid excretion was distinctly lessened. This observation has been confirmed by others, and as well for a mixed diet. It would appear that the principal result of the administration of phenylcinchoninic acid is to eliminate the uric acid of the blood by way of the kidneys, leaving the blood content subnormal. It has even been suggested that this remedy stimulates—possibly selectively—the secretion of uric acid, so constantly has this result been observed. By making use of the colorimetric (phosphotungstic acid test) for quantitatively determining the uric acid present in the blood, it has been found that as the uric acid diminishes in the blood under the influence of the drug there is simultaneously a marked increase in the uric acid contained in the urine, with an augmentation of the total amount of urine. This last statement, however, has been denied by others. The ammonia and total nitrogen in the urine may at times show a slight increase, but not at all in proportion to the marked increase of uric acid. The cloudiness of the urine which is observed during the first few hours after the administration of the remedy is due to the precipitated urates.

The action of phenylcinchoninic acid upon the kidneys would appear to be limited to that of transferring uric acid by means of these organs from

the blood to the urine, and this action, both as to the increased elimination of uric acid and the usual augmented amount of urine excreted, terminates in about nine hours.

The principal experimental work upon phenylcinchoninic acid has been done by the following: 1908, Nicolaier and Dohon; 1911, Weintraub, Starkenstein, Frank and Bauch, Deutsch; 1912, Dohrn, Plehn, Bach and Strauss, Impens, Wiechowski, Skórczewski and Sohn, Fasiani; 1913, Retzloff, Haskins, Folin and Lyman, McLester, Kehrer, Rolph, Hahn; 1914, Daniels, Fine and Chace, Steinitz; 1915, Smith and Hawk.

Therapeutics of phenylcinchoninic acid. — It should always be administered in large quantities of water. In order to prevent the formation of uric acid calculi during its rapid elimination, it is well that sodium bicarbonate be administered—one-half ounce on the first day, and from one to two drachms on the succeeding days of treatment.

Gout.—In acute attacks it relieves pain and other symptoms more promptly than colchicum, but without disagreeable after-effects, such as cardiac weakness and diarrhea. In some instances it has given prompt results even when colchicum or massage combined with hydrotherapy had failed. In the chronic forms it is often of value, especially in cases in which arthritic, myalgic, and neuralgic pains are present.

Since it has no action upon deposited urates, it is not likely to diminish the size of gouty tophi, although some clinical observers have reported this diminution as well as lessened hardness. It is often advantageous to intermit the administration of the remedy in order that the exhaustion of its action may not be encountered. Fifteen grains may be taken twice daily for three days, then one-half this quantity at the same interval for two days. After three days' interval, the series may be recommenced, for it has been shown that the initial concentration of the uric acid in the blood is again reached within from three to four days.

If it can inhibit uric acid formation by limiting purin metabolism, as has been claimed, it might be employed as a prophylactic in gout, and for this purpose fifteen grains daily, continued over considerable periods of time should suffice. Although the relations between gout, purin bodies, and uric acid have never been thoroughly understood, the accepted hypotheses are at least workable.

The uric acid problem must be attacked either by increasing the solubility of the urates in the organism, which is the method hitherto mostly in vogue; or by intensifying the fermentative uric acid decomposition, which has been studied by Brugsch and Scheltenhelm but without practical results; or, lastly, by stimulating uric acid excretion, which is the result of the administration of phenylcinchoninic acid.

Acute Articular Rheumatism.—In this disease the results of its administration, forty-five grains within six hours, are sometimes favorable in relieving pain, but it is not so satisfactory as the salicylates, although it does not cause diaphoresis, at least not a marked one, anorexia, or gastric disturbances. In addition to the relief of pain, in some instances the temperature rapidly declines and reaches the normal in from three to four days.

Chronic articular rheumatism.—In the various forms of this condition, its action is variable and at best one must expect to obtain less benefit than in the acute forms. Inasmuch as these conditions are of such varied origins, one remedy cannot be expected to accomplish uniform results.

Sciatica.—It sometimes relieves pain, but is more likely to fail. This should be expected because the causes of sciatica are so dissimilar. It has been claimed by some observers that phenylcinchoninic acid possesses analgesic properties, and it has been employed for this reason.

Clinical reports have been published by many authors, notably by Arnung, Bach and Strauss, Bendix, Bolling, Brugsch, Crofton, Deutsch, Frank, Friedeberg, Green, Goldschmidt, Grasser, Georgiensky, Heller, Hirschberg, Jakl, Kahlo, Klemperer, Lichtwitz, Minkowski, Neukirch, Oeller, Richter, Rasin, Rickertz, Salus, Sawyer, Tschernikow and Mayat, von Mueller, Weintraub, Woodward, and Zuelzer, chiefly as to the results of its administration in gout, both acute and chronic, gouty pharyngitis, acute and chronic rheumatic polyarthritis, as well as in arthritis of various types, such as arthritis deformans. Isolated reports have appeared upon its use in gonorrheal arthritis, sciatica, and other neuritic and neuralgic conditions, migraine, hemicrania, lumbago, certain forms of eczema, erythema nodosum, pruritus, iritis, episcleritis, iridocyclitis, otosclerosis, and more recently, following the vogue, in pyorrhea alveolaris.

The only untoward symptom reported following the use of this remedy, beyond a slight reduction in blood pressure, is, in one instance, a scarlatiniform eruption. The important contraindications to its employment are fatty heart, chronic alcoholism, and especially the existence of vesical or renal concretions.

We may safely conclude that phenylcinchoninic acid will doubly or even triply increase the elimination of uric acid in the urine, not because it increases its production in the body, for it does not, but because by its action, possibly selectively upon the kidney cells, it increases the permeability of the kidney for uric acid. When such an action is desired, and the instances are numerous, the remedy produces remarkable and uniformly constant results. Gout and gouty manifestations are invariably benefited; so-called rheumatism is frequently relieved—although this is merely empirical—and many other conditions of perturbed metabolism are improved. Beyond doubt, it is a valuable addition to our armamentarium.

679 MADISON AVENUE.

Autoserotherapy of Cerebrospinal Meningitis.—Capogrossi during 1917 treated 38 cases of meningitis of which at least 27 were due to the meningococcus. Of this contingent 25 were treated with intraspinous injections of meningococcus serum and the other two with autoserotherapy. Of the former 12 recovered and 13 succumbed. The cases treated by injecting the patient's own cerebrospinal fluid were desperate. While one case was not arrested, the second made a surprising recovery. Twenty c.c. of intraspinal fluid was extracted and 10 c.c. of the patient's blood serum injected.—*Il Policlinico.*

A UNIQUE CASE OF RHEUMATISM AND ITS MANAGEMENT.*

BY WILLIAM HENRY PORTER, M.D.

NEW YORK.

To meet with an entirely unique condition in these days of voluminous medical reports is an experience that comes to but few practitioners in the course of a lifetime; and to search vainly through a library of medical writings and finally to find one solitary description of a similar case in an old volume published away back in 1855, merely adds to the unique interest of this extraordinary case. It is almost with a feeling of joy that one reaches back through the years and clasps hands in spirit with an observer so shrewd, so canny in his observations, that almost we might have been discussing and describing the case which I shall now present.

It was on the 7th of January 1918, that I was called in consultation by Dr. Francis De Revere of Stapleton, Staten Island, to see a young woman of 23. On the evening of the 5th of January, Dr. De Revere had attended this young woman in her confinement. There was nothing unusual about the parturition except that the labor pains were unusually severe. The placenta was persistently retained, and after all the usual means had failed to cause the uterus to expel, the after-birth had to be forcibly removed. Every antiseptic precaution was observed in connection with the mechanical removal of the placenta. Examination of the placenta showed that it had been perfectly and completely extracted. After the expulsion of the child and up to the time of the final removal of the placenta, the flow of blood was unusually abundant. It was not sufficiently profuse, however, to produce extreme exsanguination, but was considerably more so than occurs with a normal labor. On the day following the delivery the patient was practically normal, although rather more blanched than is usually the case the day after confinement.

About midnight of January 6th, or a little more than twenty-four hours after parturition, the patient awoke from sleep. She was very restless and irritable, but had no chill. The temperature rose to 103.5° F. and the pulse to 120. About this time she complained of severe pain low down in the left hypogastric and deep pelvic regions, which rapidly increased in intensity. When seen the next day, the patient was suffering very severely. The slight pressure and light percussion of physical examination of the left hypogastrium and pelvic regions caused exquisite pain, which extended nearly up to the line of division between the hypogastric and umbilical regions. The point of greatest pain was just about the middle of Poupart's ligament and to the left of the enlarged uterine body. These symptoms increased for about three days, during which time the tumefaction in this region could be distinctly seen and felt. It was dull upon percussion. Vaginal examination revealed also a tumefaction of the vulva and vagina, and a large neoplasm of a rather dense character in the left pelvic region. This crowded the uterine end of the vagina and the uterus to the right. There was also a most distressing hemorrhoidal condition and an intense amount of congestion in the entire pelvis and rectal regions. On the third day the pathological process in the left hypogastric and pelvic region reached its height. The pain became less intense. Careful examination failed to elicit any evidence of liquefaction or the formation of pus in connection with the tumefaction.

Dr. De Revere naturally suspected infection and that we had a septic condition to combat. The lochial discharge, however, was perfectly normal as to both appearance and odor. The temperature between these three days ranged between 102.5° and 103.5°. These symptoms without chill and coupled with the fact that the patient did not have a septic appearance convinced me that we had an entirely different pathology to contend with.

On the evening of January 9, four days after the baby was born, and while still at the very height of the tumefactive development, the patient was removed to St. Vincent's Hospital, a distance of two miles from where she lived. She suffered excruciating pain during the trip. At the time of her admission to the hospital, the temperature was 102.2° F., pulse 104, respiration 26. By 12 o'clock noon the following day, the temperature had risen to 103° F., pulse to 110, respiration 26. The pulse and respirations, however, remained practically unchanged. Vaginal examination disclosed a semisolid mass on the left side which had forced the upper portion of the vaginal wall and the uterus to the right. The vulva, vagina, and rectum were somewhat less swollen.

On January 11 pain and swelling appeared in the right hypogastric and pelvic regions. It was more intense than on the left side, and the protrusion of the abdominal wall was greater on the right side than on the left. The temperature rose to 103° F., the pulse to 105; respirations, 28. The abdomen was tender up to the umbilical region. The right hypogastrium was very sensitive to the touch; the pain greatly increased upon even the lightest percussion. All over the protrusion the percussion note was dull, almost flat. The enlarged uterine body could be distinctly felt as a firm pear-shaped mass. Instead of the uterus lying directly in the median line, it was deflected to the right, especially the fundus. This was due to the pathological neoplasm which formed first in the left side, pushing the uterine body to the right and upward. When the same condition formed in the right pelvic region, there was less room for the growth, hence it rose out of the pelvic cavity and protruded to a greater extent in the right hypogastric region.

At this point, in connection with these pelvic developments, it may be interesting to note that the patient had had more or less rheumatism all her life. For six weeks prior to her confinement she had suffered severely with what had been diagnosticated as rheumatism of the right hip-joint. This condition was so acute that at times she was almost unable to get about. These facts, in connection with the clinical picture as just outlined, led me to make a diagnosis of rheumatism, instead of tacitly agreeing with Dr. De Revere, who argued in favor of its septic origin. This conclusion was amphasized in my mind by the fact that the masses were of a persistently doughy nature and showed no tendency to liquefy.

Up to this point the patient had received the ordinary treatment accorded a case of sepsis. Inasmuch as there had never been any offensive lochia, it had not been thought necesary to use antiseptic douches. The patient had received one or two hypodermics of morphine; hot stupes over the abdomen and quinine in full doses were administered for the first three or four days of the illness, with but slight improvement.

After entering the hospital she became extremely restless; therefore an ice-bag was placed upon the head and another over the right hypogastric region. The head of the bed was raised about two feet. This treatment was continued for about eleven days. The tumefaction in the left pelvic fossa gradually subsided during this period, and that on the right began to subside.

On the seventh day after admission to the hospital, the temperature dropped to normal, and remained nearly at this point until about the 11th day when it suddenly shot up to 104 deg. F. There was no increase in the pathological process in connection with this rise in temperature, neither was there any chill nor any increase in pain. Upon inquiry, it was discovered that the bowels had not moved for two days. Free calomel purgation resulted in the lowering of the temperature within the next twelve hours to 99.4 deg. F. Within the next two or three days the temperature again rose to 103 deg, but once more fell after purgation, proving conclusively that this temperature increase was due to absorption from the intestinal canal rather than from any septic condition within the pelvis.

Because of the rise in temperature and the slow resolution, and under the belief that the condition was of rheumatic origin, we decided to administer full anti-

*Read by title at the annual meeting of the American Therapeutic Society, at Richmond, Va., June 7 and 8, 1918.

rheumatic treatment, using first what has in my experience proved to be the very best antirheumatic measures. This consists in a freshly prepared solution of salicylate of sodium with iodides and wintergreen—a modification of Professor Alonzo Clarke's once famous "salicylate mixture."

R. Sodium salicylate .....dr. iii.
Sodium bicarbonate .....dr. ii.
Potassium iodide .....dr. ii.
Elixir gaultheria .....oz. i.
Glycerin .....dr. ii.
Water q.s. ad. .....oz. iv.
M.Sig. dr. ii every 2 hours, pushed until free diureais occura.

My theory of the action of the salicylates is that they arrest putrefactive fermentation in the alimentary canal. This prevents absorption of toxic matter, which is, in a measure, responsible for some of the rheumatic conditions. The profuse stimulation of the secretory functions undoubtedly carries the causative toxins out of the body, first because of the waste material flushed out through the sudoriferous glands; second, by the inhibited development of fresh battalions of germs in the alimentary canal; and third, because of the dilating influence these remedies exert upon the entire vascular system, thus drawing the blood away from the pathological zones and relieving pressure upon the nerve endings in the congested zones.

The clinical reason for my conviction is the fact that there is not adequate relief from the rheumatic symptoms until the full physiological action of the remedy is produced, but almost instantaneously following this action the case takes a pronounced turn for the better.

The unfortunate feature in connection with this most efficient therapy lies in the fact that it tends to produce an intense congestion of the stomach, which in turn causes distressing nausea and even vomiting. So pronounced is this effect that the remedy must be temporarily suspended. To obviate all loss of antirheumatic action, we utilize the iodides, oil of gautheria, and acidum acetyl-salicylicum purificatum, all of which have a similar action, and thus prevent the individual from relapsing into the same rheumatic condition while the salicylic acid mixture is temporarily suspended.

During this time the patient received a well-regulated mixed diet consisting of the folowing regimen:

For Breakfast.—Two eggs, eight ounces of milk, two ounces of wheat bread and butter.

For the Mid-day Meal.—From one-quarter to one-half pound of beefsteak, eight ounces of milk, three ounces of wheat bread and butter.

For the Night Meal.—From one-quarter to one-half pound of beefsteak, eight ounces of milk, two ounces of bread and butter.

At Bed Time.—Eight ounces of milk.

Beefsteak is taken as the working standard among the meats, as it is the most easily digested of all the food stuffs. Under the heading of meat is included lamb, mutton, occasionally veal; all kinds of fish, including the shell forms, such as oysters, clams, lobsters, crabs; poultry and game of all kinds.

The meats to be broiled, boiled or baked.

The fish to be boiled or baked.

The oysters and clams to be eaten raw or stewed. The lobsters plain boiled.

A little crisp bacon may be taken from time to time, also ham and corned beef, *without cabbage.*

Eggs may be taken boiled, poached or scrambled.

The milk is best taken warm or with a little lime-water added.

Wheat bread is taken as the standard because it is the most easily and perfectly digested. It should be at least twenty-fours old or toasted; rye, graham, zwieback, or the health food breads may at times be substituted.

Weak coffee, without milk or sugar, or with a dash of milk, may be taken freely as a beverage. Coffee taken clear aids digestion, but with milk and sugar often disturbs digestion.

Additions to Enlarge the Above Diet.—In the line of vegetables: string beans, green peas, lima beans, spinach, lettuce, asparagus, and cauliflower. These are chosen because they are the least likely to excite intestinal fermentation of an abnormal character. They should be well cooked, and only one vegetable at a meal. When a vegetable is taken with the meal there must be a reduction in the quantity of meat or milk as given in the above table. To the above may be added boiled rice, macaroni, and occasionally boiled beets, carrots, turnips, and squash.

Food Stuffs to be Avoided.—All fruits, either cooked or raw; all cereals and breakfast foods, nuts, sweets, and pastry of all kinds, potatoes in all forms, onions, tomatoes, turnips, parsnips, carrots, celery, radishes, cabbage, egg- and oyster-plant, corn, etc.; pork in all forms, except as before stated. Rich gravies, and all forms of soup are excluded. The latter, first, because they tend to destroy the keen appetite which makes possible the eating of plain and substantial food; second, because they destroy the appetite and stimulate a strong desire for the entremets and highly seasoned foods; and, third, because the mixed, cream and rich stock soups tend to excite undue and putrefactive fermentation in the intestine. Rich gravies, because they disturb digestion.

Potatoes, that are so commonly used, are excluded for three reasons: first, because they have a high percentage of starch and a low percentage of protein; second, because they are so apt to be taken three times daily, and are so often eaten fried; third and chiefly, because of the ease with which the starch contained in the potato is digested and assimilated within the system. In consequence of this rapid utilization of the potato starch, which yields to the animal economy only heat, the oxygenating capacity of the system is exceeded, and there is not a sufficient amount of oxygen left within the body to oxidize and assimilate perfectly the protein constituents of the food that must be accomplished if a perfect state of health is to be maintained. In the repair of the disease conditions it is still more necessary that the proteins shall be perfectly oxidized and assimilated, hence the absolute necessity to exclude the potatoes and food products enumerated.

Fruits are excluded, first, because they are usually picked before they are fully ripe; second, because they are in a state of partial putrefaction, and are often covered with bacterial life when eaten, and often taken in excessive quantities. Having reached the alimentary canal in this state, they excite undue and putrefactive fermentation of protein constituents contained within the intestinal canal and thus prevent the perfect digestion and assimilation of the proteid elements of the food.

When these rules are followed a good variety in the dietary can be secured, and a high grade of nutrition established and maintained.

Especial emphasis is given to the fact that red meats are never excluded from the dietary in the management of my rheumatic cases. On the contrary, my patients are encouraged to use them. Among the meats representing the animal class of food, the red meats are the most easily digested and assimilated, provided sufficient oxygen is supplied. If too much starchy food is used it often exhausts the oxygen supply before the protein can be perfectly oxidized. Wheat bread, on the other hand, holds the first place among the vegetable class so far as digestibility and assimilation are concerned.

In my opinion, a correct diet is as essential as suitable medication. As a rule, an absolutely restricted diet is not required, but an ideal mixed diet, as just outlined, is always necessary.

Improvement was manifested within forty-eight hours, and progressed steadily until the pelvic neoplasm had entirely disappeared. With the absorption of the neoplasm in the right hypogastric region a marked varicocele of the right pampiniform plexus was distinctly felt, consisting of a bunch of veins which felt like a bunch of fishing worms; this in turn also disappeared.

With the complete subsidence of the pathological process in the pelvic region, well-defined rheumatic symptoms developed in the left ankle, but these also finally disappeared under the continued antirheumatic treatment.

During the five weeks the patient was under treatment, she lost almost 75 pounds, and she became very anemic and debilitated. With the subsidence of her rheumatic attack—for that was exactly what it was—she convalesced and gained steadily, and at the end of four months had recovered the greater part of her lost weight. She is now in a fair degree of health, although still taking a stiff iron tonic and occasionally a little antirheumatic treatment.

The universal interest of this unique case lies in its rarity and in the fact that no similar condition has been recognized, except as found described by Dr. P. Cazeaux, a noted French accoucheur, in his "Midwifery." So far as I have been able to ascertain, there is not another case of this kind in medical annals. It is therefore with considerable gratification that I present the details to this society.

MODERN THERAPEUTICS IN THE NEW YORK STATE HOSPITALS FOR THE INSANE.*

By SPENCER L. DAWES, M.D.,

NEW YORK.

In my review of the newer methods employed in the treatment of the insane in the Hospitals of the State of New York I make no claim for originality, but on the contrary wish it understood at the outset that this paper is merely a collation of facts, a regrouping of statistical matter, and a different presentation of what has already been gathered, much of which has been offered to the profession by others from time to time.

It is indeed a far cry from the legislative enactment of 1788 which provided that justices of the peace might chain those "furiously mad" or "so far disordered in their senses" as to be dangerous if permitted to go abroad, to the present rule of the New York State Hospital Commission which forbids the use of the strait jacket and other methods of restraint; from the day of narcotics, sedatives, and hypnotics to that of the continuous bath, exercise, hygiene, and suitable employment; from the day of the poorhouse and the jail with the county system of maintenance to State care and maintenance under a central authority; from one State institution with a capacity of but two hundred patients in 1831 to thirteen civil and two criminal hospitals which in 1917 had a population of nearly thirty-eight thousand; from an annual expenditure of not more than $25,000 to the use of nearly $10,000,000 for care and maintenance alone.

In order to appreciate what the newer methods are it will be well to epitomize briefly what the former practice was.

Originally any insane person who was so unfortunate as to be committed was placed under arrest and pending his commitment detained in a jail or locked up in company with criminals and prostitutes, and there held with no medical supervision and later sent to the poorhouse or county asylum, if such there happened to be, where practically the only treatment he received was harshness, restraint, and the administration of narcotic drugs.

The first comprehensive step looking toward scientific care was in 1890 when an act of the Legislature provided for State care, but it was not until 1893 that all the insane were removed to State institutions, there being then 2,200 patients in the various poorhouses in the State.

To-day the law forbids the detention of the insane in jails and prisons (unless they be criminals as well) and provides that the health officer shall be responsible for the welfare of the individual pending commitment, making him responsible not only for the patients' detention but for his safety and comfort as well, and allows him to give the patient the care of a physician and a nurse. And it further provides that women patients shall not be transferred by men attendants unless such attendant be a near relative.

In a number of the larger cities of the State, notably Albany, New York, Brooklyn, and Syracuse, there are large psychopathic hospitals or wards devoted exclusively to the use of the mentally sick where they may be under observation for a time pending commitment or discharge, these hospitals or wards being in charge of trained alienists and nurses who devote themselves solely to mental cases.

Whereas under the old system the idea was custodial and the treatment was general and repressive, consisting mainly in harshness and restraint, to-day it is directly the opposite, being individual, special, hygienic, occupational, uplifting, and mentally and morally stimulating, and conducted strictly on the hospital plan.

When a person is committed to one of our State hospitals he is taken to the institution in the care of one or more specially trained nurses and frequently a physician as well, he is there carefully examined and a detailed family, personal, and medical history is taken, and he is then placed in what is known as the reception ward where he is bathed, given suitable clothes, and kept under careful observation for some little time in order that his type of psychosis, his individual idiosyncracies, and his temperament may be determined. After a period of observation he is brought before the medical superintendent and the hospital staff where he is examined, his case is presented to the staff by the physician in charge of him and after discussion by the staff, the medical superintendent determines to what ward he shall be sent and, in general, the treatment he shall receive.

Violent or excited cases which formerly were kept in restraint by means of the so-called straitjacket and the use of narcotics and similar drugs (now fortunately absolutely abandoned), yield promptly to hydrotherapy in the form of hot and cold packs, continuous warm baths, showers, spray, and douches. To this is added massage and in many cases the use of electricity.

Instead of prison surroundings we have books, pictures, flowers, music, amusement, and employment; there are drills, dancing, calisthenics, games,

*Read by title at a meeting of the American Therapeutic Society in Richmond, Va., June 7 and 8, 1918.

and theatricals, each and all under the careful supervision of physicians, trained attendants, and nurses. Most of the hospitals have large farms connected with them on which the patients may work, raising not only food but flowers as well. The kind and type of occupation best suited to the individual and his needs is selected for him after observation, such as basket making, the weaving of rugs, making of shoes and brushes, etc. There are brass workers, masons, engineers, carpenters, painters, and plumbers. Some knit, some make artificial flowers, others work in the laundry or the kitchen; they may be found pressing clothes, digging ditches, cutting hedges, setting type, printing books, roasting coffee, or doing clerical work.

One of our large hospitals roasts the coffee for all of the State hospitals and maintains a large printing establishment which does much of the printing for them all. While none of this is compulsory and all is voluntary, about fifty per cent. of the hospital population engage in some useful occupation. How much can and may be done is evidenced by the fact that in 1914 it was reported that the value of the combined manufactured and farm products that year amounted to $715,714.85. But however desirable this occupational treatment may be from an economic standpoint, that is negligible as compared to its therapeutic value, for not only is the physical well being of the patient greatly improved but his mental viewpoint is markedly changed for the better, in fact so prodigious is the improvement as sometimes to seem to be miraculous.

Patients are provided with games, such as cards, checkers, chess, dominoes, etc.; baseball is played, and contests of skill are held, while the reading of suitable books, magazines, and illustrated papers is encouraged. Religious services are regularly held at all the State hospitals, there being separate services for various sects and denominations. Each hospital has several regular visiting days on which the friends and relatives are urged and encouraged to come and see the patients, over 100,000 visits being made each year at Manhattan State Hospital alone. These visits of friends serve a twofold purpose, for they are found to have a distinctly beneficial effect upon the patients' mental condition and at the same time evidence to the relatives the superiority of hospital care over that which they could give in the home.

The dietary of the hospitals is a matter of special care and study and no effort is spared to obtain the best food the market affords, to prepare it in its most palatable and nutritious forms, and to serve it in well lighted, clean, airy dining rooms with clean linen and attractive table settings.

Most of the hospitals have cottages to which the more nearly recovered patients are assigned where they are watched over by trained attendants and physicians and where they approximate as nearly as possible to domestic and home surroundings. Probably, however, no one thing has done more to help us in our treatment of the insane than individualization—and here I can do no better than quote from a paper of the late Dr. Mabon: "Although mental disorders are diseases in which many of the principles are the same as in other diseases, we are dealing in them with more complicated symptoms and *more subtle causes*. More time is required, therefore, to study the individual patient than is often the case in other diseases. Another point is important in this connection. It used to be thought that it was possible to treat mental disorders in a wholesale fashion, but just as little as this is possible with any other disease, so it is here. To be sure, it was under this conception that the transformation of the asylum into the hospital began, and that much of the present spirit of more humane management of the patients was created, but the development went, and has still farther to go, in the direction of the individual treatment with special indications based upon the facts of each case.

"The very nature of some of the diseases with which the hospitals deal is responsible for the fact that many patients, when they come to the hospitals are chronic and a re-establishment to health is impossible, but even these offer many medical problems. Take for example the cases of paresis, one out of every four men admitted to the Manhattan State Hospital is suffering from this disease. Although the treatment of paresis is at present carefully studied with a view to a possible radical cure, these studies have not gone far enough to allow us to assume that such attempts will be successful; therefore, up to the present time the disease has been looked upon as incurable and as leading to death in a few years. It is obvious that these cases of paresis are physically as sick as any other cases with severe bodily diseases; therefore, they need constant, careful medical attention and the most skillful nursing, and it is just as absurd to think that they can be treated in a wholesale fashion as it is absurd to think that patients with, let us say, cancer, can thus be dealt with. Mere custodial care is out of the question here; and even if the physician is playing a losing game in his grappling with the disease, the present day spirit of humanity, an important asset of our civilization, will not be abandoned on that account, but everything that is necessary from a medical point of view must be done, and is done."

Senile dementia, too, is a chronic type which can be made comparatively comfortable and happy by sympathetic care and reasonable indulgence by the intelligent nurse; other types with some chronic mental change but not markedly ill physically, present such a change in their attitude toward life with their false ideas and hallucinations that they must be carefully studied by the physician as individuals to preserve in so far as possible whatever of mentality that is left. Other types present possibility for much improvement and some for cure and each one of these is carefully studied and considered by itself and its individual needs supplied wherever possible. The tuberculous patients are isolated and given the care and attention as to air, food, and rest which is considered appropriate in this disease, specialists in their lines look after the eyes, ears, noses, throats, and teeth of the patients, and skilled surgeons correct deformities and operate as needed.

As it is obvious that in order for the physician to visualize a case properly, and to treat it adequately when he has determined its needs, he must be not only experienced and apt but specially trained, so for this purpose the State has estab-

lished and maintains the Psychiatric Institute, a school to which the various hospital physicians are urged to go for the purpose of studying the underlying causes of mental disorders. At this institute also there is research work done relating to mental disease, the results of which are available to the profession at large as well as the State hospital men.

Valuable as is the training of the physician, fully as valuable is the training of the nurse and each of the State hospitals has connected with it a training school for nurses where all endeavors are made to give special instruction in the care of the mentally sick as well as in general nursing and from it are graduated a distinct type of nurse, one not only competent to care for those physically ill but especially proficient in the care of the mental incompetent.

As the patient improves, more and more liberty is granted him, and when the time seems ripe he is paroled to the custody of friends for a period of six months; his case is still carried on the hospital records and he reports at the hospital at stated intervals so that he may be advised as to treatment.

At the end of six months he may, in the discretion of the superintendent, come back to the hospital, or his parole may be extended another six months, or he may be discharged. When he has no friends the patient is looked after, helped, and advised by the State Charities Aid Association, or by the Department of After Care of the State Hospitals. Other patients remain at the hospital indefinitely but are allowed to come out and go to nearby places with great freedom. Where recovery has taken place sufficiently to warrant it the State goes so far as to seek out the friends and relatives of the patient, even though they be in other States or in distant countries, and when the State is satisfied that the patient will be wisely cared for sends him properly attended and clothed to his proper environment, and when the same is needed gives him a small sum of money for his immediate needs.

Besides all this the State maintains clinics at the various institutions where patients may come for voluntary treatment and advice and sends out physicians who give free lectures throughout the State on mental hygiene. There is also a Medical Inspector who, under direct authority of the State Hospital Commission, visits all the State and private institutions, sees and examines all patients, hears their complaints, and reports his finding to the Commission. He also investigates for the Commission all accidents, irregularities and the complaints of friends whenever such occur.

In the preparation of this paper I am much indebted to papers written by Dr. James V. May, formerly chairman of the New York State Hospital Commission, now Superintendent of the Worcester (Mass.) State Asylum, the late Dr. William Mabon, formerly Medical Superintendent of the Manhattan State Hospital, Dr. Maurice C. Ashley, Medical Superintendent of the Middletown Homeopathic State Hospital, and Dr. Walter G. Ryon, Medical Superintendent of the Hudson River State Hospital.

MORTALITY STATISTICS OF DIABETES AMONG WAGE EARNERS.

WITH OBSERVATIONS ON THE COMPARATIVE INCIDENCE OF THE DISEASE IN THE GENERAL POPULATION.

By LOUIS I. DUBLIN, Ph.D.,

New York.

Statistician, Metropolitan Life Insurance Company.

THE data on diabetes in this experience of insured wage earners* are, so far as we can determine, original in the literature of American vital statistics. In spite of the intense interest of physicians in the subject in recent years, little has been done to date to determine the extent to which the condition is responsible for mortality. The figures herewith submitted are not only accurate measures of the incidence of the disease in general, but, what is perhaps more important, give a picture of the condition in relation to economic status, sex, color, and age. To the clinician and the laboratory student of the disease, the relations presented may well serve as a clue in directing further diabetes research. Another element of interest inherent in these figures is that, referring as they do, to the industrial population, they may throw light on the probable effect of social and economic conditions upon mortality from diabetes. This is still a mooted question in the medical literature. There is a tendency in some quarters to regard the disease as more prevalent among the prosperous elements of the population. On the other hand, certain exciting causes inherent in the harsher conditions of life and work have been identified in the case histories of diabetes mellitus. It will be important, therefore, to see later how the figures here presented compare in detail with those in the general population whose economic status is altogether more favorable. It should be remembered that this number of deaths (7,762) is by far the largest aggregation of cases of this disease which have as yet received extended statistical treatment.

The following table presents the death rates per 100,000 persons exposed, among nearly fifty million "years of life," with respect to color, sex, and age period:

Table I.—Mortality from Diabetes, Classified by Color, Sex, and Age Period: Death Rates per 100,000 Persons Exposed, 1911 to 1916. Experience of Metropolitan Life Insurance Company, Industrial Department.

Age Period.	Persons.	White.		Colored.	
		Males.	Females.	Males.	Females.
All ages, 1 and over.	14 4	10 8	18.5	9 5	11 4
1 to 4	1 8	1.9	1 9		1.9
5 to 9	1.7	1 6	1.8	2	0.6
10 to 14	3 4	3 1	4 1	0 3	2.5
15 to 19	4 0	4.3	4 0	2 6	1 5
20 to 24	4 0	5.0	3 7	3 2	0 8
25 to 34	5 4	6 5	4 9	4 7	4.3
35 to 44	9 3	10 6	8 8	9.6	7.7
45 to 54	30 4	25 4	34 3	20 8	33.5
55 to 64	80 1	56.6	102 1	48 6	53.7
65 to 74	127.2	95.5	161 4	55 1	57.5
75 and over	154.9	102 1	158 2	109 8	108.9

The death rate increases with age. Between ages ten and fourteen a rate of 3.4 deaths per 100,000

*From a work in preparation: "Mortality Statistics of Insured Wage Earners and Their Families, in the United States and Canada."

persons living is the first indication of a significant distribution in the industrial population of the disease in its malignant form. Between 25 and 34 years, the rate, 5.4, accentuates the earlier finding. Beyond 35 years there is a rapid rise in the slope of the curve for diabetes. The highest point is observed in the last age period, namely, 75 years and over. But even in the more important period of 65 to 74 years the rate is not far from its maximum. In fact, among white females the maximum is reached in this period.

There is a lower death rate among colored persons at each of the age periods, and this is especially true of colored females as compared with white females. The difference in favor of colored lives becomes more important beyond age 55, when diabetes is an important cause of death. It should be noted also that diabetes has a very marked sex incidence, the rates beyond age 45 being for both white and colored women higher than for males of the corresponding race group. Prior to age 45 the sex ratio of diabetes mortality is reversed. This suggests the interesting question whether menopause may not have some influence in changing the sex ratio of diabetes mortality after 45 years of age.

Diabetes Mortality Among Insured Wage Earners and Among the General Population of the United States Compared.—Among males under 20 years of age, and among females under 35 years of age, in this insurance experience, the diabetes death rates are, almost without exception, lower than the corresponding rates for the population in the Registration Area of the United States. Beyond 20 years of age, however, there is an excess in the rate among insured white males, which increases up to the period 35 to 44. Beyond this age the excess declines to a point where the rates for the two groups are much the same. Beyond 35 years of age, there are significantly higher rates for insured women than for those in the general population. Beginning with the age period 45 to 54 years, the amount of excess varies somewhat from 25 to 30 per cent.

The following table presents the comparison for the disease in the two series; that is, the insured group and the general Registration Area population:

TABLE II.—MORTALITY FROM DIABETES. DEATH RATES PER 100,000 PERSONS EXPOSED. INSURED WHITE LIVES IN EXPERIENCE OF METROPOLITAN LIFE INSURANCE COMPANY, INDUSTRIAL DEPARTMENT (1911 TO 1916) AND GENERAL POPULATION EXPERIENCE OF EXPANDING REGISTRATION AREA OF THE UNITED STATES (1910 TO 1915). CLASSIFIED BY SEX AND BY AGE PERIOD

Age Period.	Males.			Females.		
	M. L. I. Co. (White).	U. S. Reg. Area.	Per Cent M. L. I. Co. of Reg. Area.	M. L. I. Co. (White).	U. S. Reg. Area.	Per Cent. M. L. I. Co. of Reg. Area.
All ages, 1 and over.	10.8	14.5	74.5	18.5	17.5	105.7
1 to 4.....	1.9	2.2	86.4	1.9	1.8	105.6
5 to 9.....	1.6	3.0	53.3	1.8	3.0	60.0
10 to 14.....	3.1	4.2	73.8	4.1	4.8	85.4
15 to 10.....	4.5	4.8	93.8	4.0	4.1	97.6
20 to 24.....	5.0	4.8	104.2	3.7	3.8	97.4
25 to 34.....	6.5	5.6	116.1	4.9	5.2	94.2
35 to 44.....	10.6	8.6	123.3	8.8	8.3	106.0
45 to 54.....	25.4	22.6	112.4	34.3	27.5	124.7
55 to 64.....	56.6	57.4	98.6	102.1	78.4	130.2
65 to 74.....	95.5	95.0	100.5	161.4	127.9	126.2
75 and over.....	102.1	112.8	90.5	158.2	121.2	130.5

Trend of the Death Rate from Diabetes.—In this experience for insured wage earners there is a slight tendency toward increase in the recorded death rate for diabetes mellitus. There is some significance attached to this increase in mortality from the disease. There are no important diagnostic considerations confusing the statistics for diabetes as may be observed for several of the other diseases and conditions, notably cancer. Fatal diabetes is well reported in this mortality experience, and the certification of the disease has probably not improved materially during the period covered by this experience. The minimum rate was observed in 1911, 13.3 per 100,000 persons exposed. The group of insured white females was very largely responsible for the high figures shown in 1916 in the entire experience. In 1911, insured white females registered a diabetes rate of 16.5 per 100,000 exposed; in 1916 the figure was 20.2 per 100,000.

In the experience of the Registration Area of the United States also there has been observed since 1900 a gradual increase in the death rate of diabetes mellitus.

The figures for the individual years are shown herewith by color and sex:

TABLE III.—MORTALITY FROM DIABETES, CLASSIFIED BY COLOR AND BY SEX. DEATH RATES PER 100,000 PERSONS EXPOSED. SINGLE YEARS IN PERIOD 1911 TO 1916. EXPERIENCE OF METROPOLITAN LIFE INSURANCE COMPANY, INDUSTRIAL DEPARTMENT.

Year.	Persons.	White.		Colored	
		Males.	Females.	Males.	Females.
1911 to 1916	14.4	10.8	18.5	9.5	11.4
1916.....	15.9	11.5	20.2	11.6	14.8
1915.....	15.1	10.3	20.0	8.1	14.4
1914.....	14.2	10.5	18.4	10.0	10.4
1913.....	13.9	10.8	17.5	8.9	10.9

1911.....	13.3	11.3	16.5	8.1	7.7

THE ORIGIN OF THE SO-CALLED "SPANISH INFLUENZA."

BY JAMES JOSEPH KING, A.B., M.D.,

NEW YORK.

CAPTAIN MEDICAL CORPS, U. S. ARMY.

WE desire to present in this preliminary note a consideration of the similarity of the present epidemic to the epidemic of pneumonic plague which broke out in Harbin, China, in October, 1910, and spread rapidly and continuously throughout Northern China at that time; and to suggest that this epidemic may be the same disease modified by racial and topographical differences. The origin of this epidemic was suggested to the writer soon after its outbreak in our camps by Mr. Guy M. Walker, an eminent American authority on Chinese affairs. This suggestion led to an investigation of the reports of the pneumonic plague in China and there is sufficient likeness of that epidemic to the present one prevailing in our cities and army camps to warrant a consideration of it.

In the latter part of 1910 the pneumonic plague first appeared in Harbin, a town in Manchuria under Chinese control. Harbin is on the Trans-Siberian Railroad, and was the original hotbed

of the disease. The plague had prevailed in Russia previous to November, 1910, but the Russians, alert to its danger, took immediate action and stamped it out. It was believed that the plague was carried into Harbin by the fur dealers and by Chinese laborers returning to their homes to celebrate New Year's Day, a custom universally observed in China. From Harbin the plague rapidly spread in all directions, usually following the lines of traffic along the railroads. It spread as far south as Chefu, a seaport town, probably having been carried there by Chinese coolies returning from the north.

By January 24, 1911, 1,500 Chinese and 27 Europeans, two of whom were physicians, and one an assistant, had died of it. Nearly all who had the disease died of it.

This plague has been very serious. The mortality has been fearfully high. It has spread throughout China. Wherever the Chinese coolies from the North have traveled they have carried this disease. From 1910 up to 1917 China has not been free from it. The writer has heard of several cases being present in Peking last year.

In the early part of 1917, about 200,000 Chinese coolies, collected from the northern part of China, where the pneumonic plague has raged at intervals since 1910, were sent to France as laborers. Part of them were sent around through the Mediterranean; some, and perhaps the majority, were sent across the Pacific, and then through Canada and America, to be transported across the Atlantic to France. Trainloads of these coolies were sent in solid trains across the United States to New York and thence to France. They made splendid laborers in France, and were in back of the lines during the German drive of March, 1918. No doubt many of them were captured by the Germans at that time. Hence the outbreak of it in the German army and its rapid spread in Spain.

So far as we know, this disease first broke out last spring, in the German army, where it is said to have been very serious. We next heard of it in Spain, hence the name Spanish influenza. The name is really a misnomer, but it has stuck probably because it is the first epidemic of influenza that Spain has ever had. Since our soldiers and sailors have been returning from the battlefields of France it has become very prevalent and serious in our camps and cities all over this country.

We wish, after the brief review of the pneumonic plague and the narration of its possible connection with the present epidemic, to compare the diseases both clinically and from a bacteriological standpoint.

It is not necessary here to go into detail concerning the clinical data, except in a very general way. In the China epidemic there were few definite symptoms at the outset of the disease except the general malaise, prostration, loss of appetite, etc., soon to be followed by the pneumonic process and death. So it is in the present epidemic. There have been indefinite symptoms, great prostration rapidly followed by pneumonia and death in the most virulent forms. The outstanding features of the Chinese pneumonic plague were the high infectivity of it and the high mortality. So in this so-called influenza epidemic it is more contagious, is followed more frequently by pneumonia, and attended with a much higher mortality than in any previous influenza epidemic.

In the pneumonic plague epidemic of China the *Bacillus pestis* was almost constantly found associated with the pneumococcus and the streptococcus. It is reported that different strains of these organisms were found in different localities where the plague was prevalent, and the virulence of the disease likewise varied. For instance, Dr. Shibayama made a report on eight different strains of pneumonic-plague organisms before the International Plague Conference in Mukden in 1911.

The bacteria found in patients in the present epidemic have been the influenza bacillus associated with the four groups of pneumococci, the *Streptococcus hemolyticus*, and the *Micrococcus catarrhalis*. For instance, in one camp the organisms found have been the influenza bacillus associated with Group 1 pneumococcus; in another it has been the influenza bacillus associated with Group III pneumococcus; in another, influenza and *Streptococcus hemolyticus*, etc. We see, therefore, how different strains of the pneumococcus and streptococcus associated with a bacillus are the exciting causes of the epidemic in different localities. Likewise, the mortality and virulence of the disease vary in different localities.

Thus we have shown a striking similarity between the pneumonic plague of North China and the present so-called Spanish influenza epidemic. It is not unreasonable to believe that the two diseases may be the same. The influenza bacillus and the *Bacillus pestis* in atypical forms may simulate each other. We know that organisms may assume different forms and have different cultural characteristics in different conditions. The ordinary influenza bacillus is a short, slender bacillus. The plague bacillus is about the same length, but is generally fatter and broader; both are Gram negative. It seems possible that the *Bacillus pestis* may have been present in a non-virulent state in the Chinese coolies, and assumed new virulence, vigor, and a somewhat different form, when transplanted into virgin soil. The high mortality and infectivity of this epidemic strongly suggest it.

On this basis the epidemics which have followed all great wars may be explained. If a nation or tribe can survive any disease long enough it will acquire immunity to that disease. When, however, foreign people commingle freely and intimately, as in war, epidemics will break out. The inactive, non-virulent organisms in one race will become virulent in some other race which has not acquired immunity to that specific organism.

We therefore present this comparison for the serious consideration of the profession. A very grave situation confronts us. Every patient with this epidemic should be quarantined, and everything possible should be done now at its ontset to prevent its spread.

THE ACTION OF CHLORINE ON SUTURE MATERIAL.

By GEORGE L. SERVOSS, M.D.,

RENO, NEV.

WITH the introduction of chlorinated lime and its modifications as antiseptics, we are told that these things can be employed in much the same manner as are corrosive sublimate, phenol, and the phenol compounds, and other stable chemicals of the latter sort. We are told that when suspicious of possible wound infection we can apply dressings wet with solutions of these chlorinated mixtures or compounds. In fact, we are told to go ahead with practically the same technique as we had been employing, simply substituting the chlorinated mixtures or compounds for the staple antiseptics. That sounds plausible on first thought, for it is a known fact that the chlorinated antiseptics do destroy germ life and are effective. But there is another, and, it seems to me, rather important factor in the case. Free chlorine is destructive to both animal and vegetable matter, if that matter be dead. Consequently, free chlorine is very liable either to destroy suture material or to render it worthless. This had not entered my mind, even though I knew what bleaching powder did to fabrics, until a case in which I employed a wet chlorinated dressing forced the idea upon me that such technique was all wrong. The following is the history of the case:

A young boy, while playing tag in a swimming pool, was struck over the left eye by a flying ring which had been propelled in his direction by one of his playmates. A wound about an inch long, to the bone, was made through the eyebrow. This was sutured with one silkworm-gut stitch in the center and with two 20 day chrome-gut stitches on either side of the center and, being supposedly an infected wound, a couple of strands of the chrome-gut were placed, for drainage, in the outer angle of the wound. A wet dressing of gauze, wrung out of a solution of one of the chlorinated compounds, was applied. The percentage employed was the one suggested in such cases. Union by first intention obtained. At the end of ten days I started to remove the stitches. Silkworm-gut, at the end of such interval, usually requires removal by cutting away. In this instance, when picking up the stitch, preparatory to putting the point of the scissors underneath, *the silkworm gut came away, as would plain catgut at the end of such interval;* I then lifted the chrome gut and it *came away without the necessity of cutting.* The drainage strands also lifted off at their point of exit from the wound.

This opened my eyes to the fact that something was wrong, for I had never seen silkworm gut act in that manner, and had seen 20-day chrome gut, under other dressings, and even wet ones, cut away at the end of ten-day intervals. Believing that the free chlorine had had some effect upon all the suture material, I placed strands of silkworm gut, twisted silk, and plain catgut in the same percentage solution of the chlorinated compounds, and other strands of the same materials in a tube of plain water as a control. These were left for ten days, during which time the air temperature was about that normal to the body. At the end of the interval I found that while the appearance of the silkworm gut and silk had not changed, they were absolutely useless for any purpose whatsoever. Bending, even so slight, caused breaking of the silkworm gut, and the least pull on the twisted silk had the same effect. The catgut in the chlorinated solution seemed to have undergone a sort of digestion, and had fallen to the bottom of the tube in a fluocculent mass. In the control tube the usefulness of neither the silkworm gut nor the twisted silk had in the least been affected. Of course, the plain catgut was more or less macerated, as had been anticipated, but it had not been affected, as had that in the chlorinated solution.

I understand, following replies to inquiries made by me to men who have had more or less experience with the use of the chlorinated solutions, that experience reaching over a number of years, that others have seen sutures become useless under like conditions. I have been told that such things have been reported in years gone by, but such reports have either been lost or overlooked, it would seem. If not, then the instruction that chlorine solutions may be employed with a technique similar to that used in connection with the staple antiseptics which do not destroy suture material, would seem to me quite wrong. In a wound such as was present in the case reported, and in which there was no great stress or gaping, the giving away of the sutures might make no material difference, but what might happen in a large abdominal wound, where the pull on the borders thereof might be considerable? It may be admitted that a sterile open wound might be the result, but it would not be a very pleasant condition for the surgeon to confront. I am reporting this because I feel that it is something of more than passing interest—something that may serve to save one or many surgeons much embarrassment in time to come.

Medicolegal Notes.

Effect of Express Contract to Pay for Services to Another.—In a suit on an implied contract for service rendered by the plaintiff hospital in caring for the defendant after he had been injured while working for a company, evidence as to an agreement of the manager of the company to pay hospital expenses was held admissable to show an express promise to pay the plaintiff. It was immaterial whether the manager had authority to bind the company, since if he did not he would bind himself. The company's express promise being shown, no promise implied in law, arose on the part of the defendant injured man.—Brightlook Hospital Assn. v. Garfield, Vermont Supreme Court, 104 Atl. 99.

Unlawful Importation of Opium.—The Harrison Drug Act of 1914, imposing a special tax on all persons who produce, import, manufacture, compound, deal in, dispense, sell, distribute, or give away opium or coca leaves or their derivatives, did not in any way affect the Act of Jan. 17, 1914, c. 9, amending the earlier Act of Feb. 9, 1909, c. 100, prohibiting the importation of smoking opium, and declaring a presumption of the illegality of the importation of such opium.—Gee Woe v. United States, 250 Fed. 428.

Accident Insurance—Cerebral Hemorrhage.—Under an accident insurance policy exempting the insurer from liability for disability caused by cerebral hemorrhage, where the insured accidentally fell, striking his head and rupturing a blood vessel in his brain, causing cerebral hemorrhage, which caused partial paralysis and a total disability for eight weeks, it is held that he could not recover from the insurance company on the ground that paralysis resulting from external bodily injury was the proximate cause of disability.—Order v. Dobbs, Texas Court of Civil Appeals, 204 S.W. 468.

X-Ray Photographs in Evidence—Authentication.—In an action for personal injury, the admission of x-ray photographs in evidence, without proof that they were correct portrayals of the injury, is error.—Kansas City M. & O. R. Co. v Swift, Texas Court of Civil Appeals, 204 S.W. 135.

Military Medicine.

TUBERCULOSIS IN FRANCE.

The fear expressed by Americans that their expeditionary forces may be infected on French soil with tuberculosis has given a new impetus in France to the warfare against this disease, and statistics are in demand respecting progress in the campaign. According to Meslier, writing in the *Journal de Médecine de Bordeaux*, the number of soldiers evacuated for tuberculosis from the beginning of the war up to October 31, 1917, is computed at nearly 90,000. But owing to duplication of cases and other sources of error 60,000 is much nearer the mark. The latter figure, however, does not include the tuberculous exchanged prisoners, which according to Swiss physicians numbered 30 per cent. of the whole.

All antituberculosis activities are now centralized, and comprise sanitary hospitals, sanitary stations, and auxiliary committees. On November 30, last the number of hospital beds available for consumptive soldiers was 6,521. The first examination is made in the garrison hospital or patient's home, the second in the sanitary hospital in which the nontuberculous are weeded out, and the tuberculous appropriately treated. If the patient is cured he is discharged, and if convalescent spends three months at a sanitary station where he learns how to care for himself. He is then discharged and returns home where he remains subject to the control of the local auxiliary committee.

The sanitary stations, with thirty departments, control 4,000 beds, making the grand total over 10,000 beds for consumptive soldiers. The function of the auxiliary committees consists largely in contributing in various ways to the maintenance of the consumptive and his family. The money for this purpose is raised by subscription and appropriation, and some departments have as high as 200,000 francs available at one time. There is still another provision made for old soldier consumptives, through the activities of a national committee which lends assistance to the departmental auxiliary committees, the funds of which amount to 3,000,000 francs. The sanatoria for consumptives, which form the ideal resource in antituberculous warfare, do not figure at all in the campaign, for they cannot be improvised, and the activities which could call them into being are fully employed as above outlined.

It may now be asked whether these resources are properly utilized. The writer says that the answer to this must be No. The real problem is one of early diagnosis, and without this no organization can solve it. Again, the disease is on the increase, not only among the troops, but in the civilian population. The causes must be sought and removed. So far as the author can judge military hardships which are unpreventable operate adversely among the troops and so long as men are evacuated home with open tuberculosis they infect the civilians. Just what the actual condition is, however, it is difficult to determine, for the total number of deaths annually from the disease in France has been reckoned as high as 150,000 and as low as 80,000.

The Cafard Again.

About a year ago the word "cafard" began to be recognized among the neologisms coined by the French soldier. It expressed a peculiar mental state which was described at the time in the Medical Record along with the etymology of the word. Since that period the subject has undergone a certain evolution and recently Voivenel, regarded by his medical colleagues as one of the most gifted writers in the profession, has taken up the problem of cafardism in a brochure in collaboration with Huot. The cafard soldier, who seems at first view a shammer and is hence given a nickname with the primary meaning of hypocrite, is in reality a victim of a psychoneurosis due to prolonged and arduous military life. He is a victim at once of abulia and impulsive acts, both defects springing from a common cause. This syndrome antedates the present war, for it has been seen in the colonial soldier. Otherwise stated, a man who has become adapted to a difficult environment finds himself "disadapted" again—a condition not readily visualized in the absence of a severe illness or similar experience. The work of Huot and Voivenel is reviewed in *Le Progrès Médical* for July 27 by Satre. The picture of cafardism differs from the earlier descriptions, for in some cases there are visual or auditive hallucinations which play a rôle in the evolution of the mental state. A physical basis of the condition which is sometimes seen as one of the asthenias, suggests a possible exhaustion of the adrenals. One might have accused a relaxed state of the tone of the splanchnic nerves at an earlier period of our knowledge. However, it is not uncommon to see soldiers who are the picture of health and vigor suffer with marked abulia. It is the appearance of the cafard in this healthy soldier which makes the problem one of such unusual interest—in fact, such behavior in a neurasthenic or psychasthenic would not tempt study, for we are not surprised at anything such subjects do. To see a normal soldier with a good record commit senseless breaches of discipline because he cannot inhibit his desires is in itself sufficient to create a new problem in military life. It must be remembered that these subjects have not been shell shocked or undergone any sudden catastrophe which could have temporarily upset their equilibrium. It is just the lack of motivation that gives to the behavior its mysterious quality. It may some day be possible to understand this condition, which is at present so obscure.

Military Service and Insanity.—Colonel Pearce Bailey, writing in *Mental Hygiene*, July, 1918, on the care and disposition of the insane, has the following to say regarding military service and insanity. The diminished percentage of insanity in any army systematically examined with the view of eliminating those who might become insane seems to contribute something to the answer of a question of military psychiatry which has never been satisfactorily answered. The question is this: Does army life make men insane? The question is especially important in a warfare which involves the whole nation, as bearing upon the economic value of psychiatric examinations. So far as

epilepsy and mental deficiency are concerned, the present statistics do not throw much light. While camp conditions might easily, and as a matter of fact often do, give rise to nervous episodes in the mentally deficient, they have nothing to do with the underlying cause. The same may be said of epilepsy. The frequency of attacks in epileptics may be increased after entering the army, but figures so far obtained do not justify the assumption that a potential epileptic under peace conditions is converted into an actual one by army life. But the matter is quite different with the psychoneuroses, constitutional psychopathic states, and dementia præcox. It seems that even in the training camps any of these conditions may become active and conspicuous through the requirements of military service when they had not manifested themselves to a degree to be incapacitating in civil life. It is not believed that this conversion of a potential psychosic into an actual one in the camps is a result of hardship or physical causes. It is believed rather to be a psychological result of disharmony with new and rigid conditions which the neurotic, who is intensely individualistic, finds it impossible to adapt himself to and so breaks down. This explanation holds true for those who have volunteered quite as much as for those who have been drafted.

So far as the expeditionary forces are concerned, the time has not yet come to explain the method of production of psychoses. Most of the wounded so far returned had departed for France before the neuropsychiatric examinations had been established. Among them there is a percentage of nervous and mental disease of twenty-five, a percentage that seems destined to decrease as the figures more and more concern the examined army. The experience of Bailey and coworkers indicates that a pronounced psychopathic constitution and military service are antagonistic. It is believed, on the other hand, that psychoneurotics who might render excellent service in their civil capacity become incapacitated by the change in their habits of living however patriotically they may have sought it. It is also believed that the army fares better without them, although instances may be brought forward to prove the contrary. Great generals may be cited as epileptics, great leaders who were fanatical to the point of insanity, and others who with unmistakable symptoms of psychoses were nevertheless famous strategists; but these exceptions are rare and do not affect the rule, now well established, that those expected to work effectively and harmoniously under the order of others must be of sound nervous system.

Classification in the Volunteer Medical Service Corps.—Interest among the members of the medical profession as to how their services are to be used in the Volunteer Medical Service Corps, once they have been enrolled and have put on the badge which indicates their willingness to serve and readiness to respond to a request from the Surgeons General of the Army, Navy, or Public Health Service, or from the Provost Marshal General, or from the General Medical Board of the Council of National Defense, has led to the announcement by the Central Governing Board of the basic system of classification for the organization. The lines on which the classification is made were determined by the Committee on Classification of the General Governing Board, and whose report was adopted. This Classification Committee has on it representatives of the Army, Navy, Public Health Service, Council of National Defense, American Red Cross, Hospitals, Colleges, Civilian Doctors, War Industries.

CLASS I.—These will be the physicians first recommended by the Central Governing Board to apply for commissions in the Medical Reserve Corps of the Army, Reserve Force of the Navy, or for appointment in the Public Health Service. They include physicians under 55 years of age who are without an obvious physical disability which is disqualifying, and who have not more than one dependent in addition to self; or who have an income, or whose dependents have an income, sufficient for the support of dependents other than that derived from the practice of their profession.

There are several exceptions provided for because of evident essential needs. Whether a physician's services are essential to his community will be established by the Central Governing Board on recommendation of representatives of the board appointed by it to make a survey of local conditions. Whether a physician is essential to an institution with which he may be connected will be established after conference between representatives of the Central Governing Board and representatives appointed by governing bodies of the institutions concerned. Similarly, the question of whether a doctor is essential to a health department will be established by conference between the Central Governing Board and the head of that health department. The question whether a teacher in a medical school is essential to that position will be established by the Central Governing Board and representatives of the institution. Conference between the board and accredited representatives of industries concerned will determine whether doctors employed as industrial physicians are essential in those positions. A physician essential on his local or medical advisory board will not be disturbed.

CLASS II.—In Class II are physicians under 55 years of age who are without an obvious physical disability which is disqualifying and who have not more than three dependents in addition to self. These will be recommended by the Central Governing Board, when the need exists, to apply for commissions. Exceptions in Class II are the same as in Class I.

CLASS III.—These are physicians under 55 years of age who are without an obvious physical disability which is disqualifying but who have more than three dependents in addition to self; and they are the physicians included among the exceptions from Classes I and II, namely, those essential to communities, institutions, health departments, medical schools, or industries. They will be recommended by the Central Governing Board to apply for commissions when the emergency is so great as to demand their services.

CLASS IV.—In Class IV are the physicians who are ineligible for commissions in the Medical Reserve Corps of the Army or Reserve Force of the Navy, but who are available for all other services. The physicians in this class include those over 55.

those having an obvious physical disability which is disqualifying, and those rejected for all Government services because of physical disability.

Physicians not professionally eligible for the Medical Reserve Corps of the Army or for the Reserve Force of the Navy or for appointment in the Public Health Service will be recorded but not admitted to the Volunteer Medical Service Corps.

Applications for enrollment in the Volunteer Medical Service Corps continue to come in from physicians from all over the country, and by every mail, to the headquarters at the Council of National Defense Building. These are being classified as rapidly as possible. Representative physicians from various parts of the country are assisting in the work incident to the classification. State Executive Committees, enlarged to handle the work of the Volunteer Medical Service Corps, are perfecting the organizations in their States, and county representatives have been appointed in practically every county in the country. Group meetings are being held in many of the States, at which the State Executive Committees and county representatives are being addressed by members of the Central Governing Board of the Volunteer Medical Service Corps.

President Wilson Nominates New Surgeon-General.—President Wilson has nominated Major General Merritte W. Ireland of the Medical Corps to be Surgeon General for the four years beginning October 4, 1918, Major General Gorgas being retired on reaching the age limit. General Ireland was head of the medical department of the army in France prior to his appointment as surgeon-general.

Influenza and Pneumonia in Army and Navy.—Reports received by the War Department from camp surgeons show that on October 3, with three camps, Sherman, Taylor and Jackson, not heard from, the number of new cases of influenza was 12,004, bringing the total of all cases reported by all camps since September 13 to 113,737. Ten camps reported an increase in the number of cases, while the remainder showed decreases. The greatest number of new cases of pneumonia, 133, was reported from Camp Grant, with 31 deaths. Of the 2,000 students at the United States Naval Academy at Annapolis, between 700 and 800 have been stricken with influenza, and thus far there have been three deaths attributed to the disease. The transportation of nurses and nurses' aids from this country to the American hospitals in France has been stopped by the Surgeon General's office until the epidemic of influenza in this country has been conquered. The order also provides that nurses and their assistants will not be received into the training camps on this side until the danger of the disease is passed. Influenza has also spread to Canada, the first death from the disease occurring in the military hospital at Hamilton, Ontario, where there are more than 100 cases.

Increase in Pay of Army Nurses.—The Senate has passed a measure increasing the pay of all chief nurses in the army $10 a month and providing for the payment of salaries of all army nurses while prisoners of war.

Red Cross Recruits More Nurses.—All women who have had any kind of nursing experience are urged to register for service with the Red Cross at the bureau established at 389 Fifth Avenue, New York. A call has just been sent out for the mobilization of all nurses and women possessing even elementary knowledge of the care of the sick.

Physician Gives Convalescent Soldiers and Sailors Outing.—Dr. John A. Harriss, Special Deputy Police Commissioner of New York City, acted as host, on October 1, to 150 convalescent sailors from United States war ships on duty in foreign waters, and 100 marines who are recovering from wounds received in the fighting around Château Thierry. The patients were taken by automobile to Dr. Harriss's steam yacht which conveyed them to his summer home at Collender's Point, Conn., where they were provided with entertainment in the form of a concert and a shore dinner.

Medical Officer Loses License.—The Board of Regents of New York State has revoked the license of an Albany physician who was a captain in the United States Army, after he had been found guilty under the Federal law of accepting money to influence his decision in a matter pending before him officially.

Foreign Branches of Red Cross.—The American Red Cross. in the fifth installment of its war fund statement, gives the report of the Fourteenth or insular and foreign division of the American Red Cross. This division is not yet a year old, but has about 150 chapters and branches, among which are chapters in the South American countries, Hawaii, the Philippines, Spain, Sweden, and Switzerland. To the first war fund this division gave $267,462 and to the second $1,710,000. The South American countries made substantial contributions to these funds and Cuba, in the second drive, gave $155,000. Hawaii, in the latter part of 1917, contributed $200,000 and in the second drive $677,000. China, in the second drive, gave $100,000.

Work of the Red Cross for Civilian France.—The American Red Cross, in a recent installment of its report to the American people concerning the use that it has made of its war funds, states that in carrying out its work in France, in all its activities, it expended up to July 1, 1918, the sum of $36,613,682.73. Of this amount, $15,453,049 was apportioned to relief work among the soldiers and strictly military activities. The balance was appropriated to relief work among refugees, the fight against tuberculosis, and other civilian relief work. The demand for the six months ending December 31, 1918, has seemed greater than at any other period, and an appropriation has therefore been made for this period amounting to $43,582,827, of which $20,753,410 is for relief among refugees, rehabilitation of devastated areas, the fight against tuberculosis, and other civilian activities. In the relief of refugees, of which there have been more than 400,000, the Red Cross has expended nearly $3,000,000. Up to June 1, 1918, the appropriation for the fight against tuberculosis totaled $2,147,327. It is estimated that of the 80,000 French babies who died last year 40,000 might have been saved by proper care. To meet the need for child welfare work, $2,775,877 has been appropriated for the period ending December 31, 1918. For the period ending June 30 the appropriation was $1,149,129.

New York, October 12, 1918.

SPINAL ANESTHESIA BY "BARBOTAGE."

By the use of a peculiar method of injection, Dr. Fillistre (*Paris Médical*, June 15, 1918, No. 24) has succeeded in obtaining anesthesia of the entire body. The number of cases in which the "barbotage" method, as he calls it, has been applied by Fillistre is over 2,000. To judge by the diagrams, the needle, fifteen centimeters in length, is as fine as that used by Corning in 1885. The point selected for the injection is the space between the last lumbar and the first sacral vertebræ. Cocaine has seemed to be the best agent for this generalized anesthesia. The higher up it is purposed to extend the area of anesthesia the greater—within the limits of safety—should be the amount of cocaine injected. So, too, with regard to the withdrawal of cerebrospinal fluid: less should be taken to anesthetize to the level of the umbilicus than when it is sought to extend the zone of insensibility to the thorax, upper extremities, or head. In accordance with this principle, the quantity withdrawn varies from 20 to 30 c.c. Moreover, the fact that the fluid issues from the needle freely, or dribbles forth drop by drop, has its influence. In the first event somewhat more is withdrawn than in the second.

After the injection of the anesthetic—and we come now to the distinctive characteristic of the method—the piston of the syringe is moved to and fro several times ("barbotage," from "barboter," to dabble), the apparent intent of this maneuver being to further a more complete diffusion of the anesthetic in an upward direction. This done, the patient is told to lie down, and is not allowed to raise his head during the operation or for a considerable time thereafter. Extraneous to the method, strictly speaking, is the injection of scopolamine, morphine, spartein, and strychnine some little time before the operation. Among the more conventional recommendations are silence in the operating room and bandaging the eyes of the patient.

It is noteworthy that before applying this method in human beings Fillistre instituted some interesting experiments. In the apparatus employed, a glass tube nearly filled with water was so arranged as to represent approximately the conditions surrounding the cord. By means of a syringe attached to the inferior end of the tube, and charged with a colored liquid, repeated movements of the piston caused the color to be quickly diffused throughout the column of water.

Subsequently, invoking the method in the human subject, Fillistre ascertained that cocaine alone could be made so to diffuse itself as to bring about a general analgesia of the whole body. Stovaine and novocaine, on the contrary, rarely produced a region of anesthesia extending beyond the umbilicus. Finally, increasing the size of the syringe augments the effectiveness of the "barbotage."

GASTRIC AND DUODENAL ULCER AND CHRONIC APPENDICITIS.

It has long been known that severe maladies on the border line of medicine and surgery are prone to appear in the digestive tract simultaneously. In many cases this sort of incidence makes diagnosis impossible in the absence of exploratory laparotomy. It is common enough in gastric and duodenal ulcers to find other lesions in the small and large intestines, including chronic appendicitis, and such associations must represent something more than coincidence. Dubard (*Journal de médecine et de chirurgie pratiques*, April 25) has recently analyzed a large number of operative cases from this viewpoint, with control by medical examination and the *x*-ray. He has one series of 145 gastroenterostomies. Of these, 44 were operated on in a temporary hospital, and, deducting 8 cases in which the lesion was pyloric cancer, there remain 36 for ulcer and retention of the pylorus. In no less than 12 of these 36, chronic appendicitis was associated, so that appendectomy was superadded to gastroenterostomy. The subjects were all men of military age—21 to 45. In civil practice the percentage of associated appendicitis is even higher.

In the other series of 101 gastroenterostomies, done in regular city hospitals, 40 were performed for ulcer at or near the pylorus, including duodenal ulcer; and among the cases were 18 of appendicitis, or 45 per cent. Of the balance, 48 interventions were for cancer of the stomach and the balance for affections of the gall bladder. (The author makes a practice of adding gastroenterostomy to operations on the gall bladder and choledochus.)

What is the bond of unity between chronic appendicitis and pyloric (juxtapyloric) ulcer? For sixteen years the author has studied this question. Is it some common cause like the tubercle bacillus? In his material there was evidence of past tuberculosis universally present, but the lesions could hardly have been bacillary. The men had either overcome the early tuberculous infection or rendered it latent. In nearly every case there was sensitiveness to pressure over the pneumogastric nerve, either on one or both sides, suggesting the tenderness of the sciatic nerve in sciatica. The diagnosis of past tuberculosis was based on careful examina-

tion by internist and radiographer. There was a correspondence between the sensitive nerves and the formerly diseased apices. The pressure test on the former was naturally made at the side of the neck; and the degree of sensitiveness was often exquisite. The author employs the test in general routine, and in dyspepsia, in the wide sense of the term, has found it present in 8 per cent. This induced sign means for its discoverer a neuritis of the vagus dependent on the tuberculous lesion, and having as a consequence an increased susceptibility to lesions and disorders in the abdominal distribution of the nerve. The changes which make possible the supervention of pyloric ulcer are essentially trophic. The anthor's theory of a neuritis of the vagus was upheld in the only histological case available.

If the author's view is correct, we have an easy explanation of the persistence of symptoms after appendectomy and gastroenterostomy. The sufferings of the patient being the result of the vagus neuritis, operation does not touch them. Polyalgias are a necessary consequence of the neuritis.

THE DIAGNOSTIC VALUE OF PAIN IN ABDOMINAL DISORDERS.

When one is in the presence of a true duodenal ulcer the gastric symptoms are so attenuated that the practitioner may be led to suspect a chronic appendicitis or cholelithiasis, rather than the real nature of the lesion. In numerous writings, Paterson has attempted to differentiate clinically between duodenal ulcer and chronic appendicitis, but he does not limit himself to typical duodenal ulcer. However, by a detailed analysis of the various symptoms of ulcers and appendicitis the clinical differentiation between the two processes can usually be made.

In chronic appendicitis, as in duodenal ulcer, the pain may be felt in recurring paroxysms. In certain forms the predominating digestive disturbances consist of epigastric pain, occasionally with periodical exacerbations, acid eructations, and an increase in the acidity of the gastric juice, so that the diagnosis may well be difficult. In order to arrive at a correct conclusion an entire group of symptoms should be present, although any one of them may be wanting, but each one which exists gives more value to the general conformity of the diagnosis. In point of fact, there is not a single diagnostic sign which may not be misleading.

In the first place, the provoked right-sided pain in appendicitis should be deep-seated, and constant over McBurney's, Morris' or Lanz's points, persisting in the form of lameness after cessation of pressure, and set up by deep pressure made on the left side of the abdomen, which causes dilatation of the cecum by forcing the intestinal gas into it. Spontaneous pain has no absolute diagnostic value, while irradiations of both spontaneous and provoked pain are occasionally so acute that they may lead to an erroneous conclusion as to their starting point. Thus the irradiated pain in the epigastrium, very frequent in the gastric forms of chronic appendicitis, may lead to the suspicion of a gastric or duodenal ulcer, but in this case, if a finger presses upon McBurney's point while with the other hand the examiner searches for sensitiveness in other areas, the principal site of provoked pain can usually be detected.

The difficulty of localizing pain in the right umbilico-iliac area is well shown in a paper by Loeper and Esmonnet (*Bulletin médical*, May 28, 1910), who divided the abdomen into a series of areas of sensitiveness corresponding to various sympathetic chains. The principal points are the epigastric; the upper mesenteric, which corresponds to Morris' point, and represents the small intestine and the right half of the colon; the lower mesenteric point, three centimeters from the midline and three centimeters below the umbilicus; the solar plexus area, corresponding to the umbilicus and periumbilical area; and lastly, the aortic point, situated between the mesenteric points and promontory. In relation to the deep-seated viscera, these points reveal pain the causes of which are most varied, while their multiplicity on the right side of the abdomen indicates the delicacy of a diagnosis based on pain in this region.

On the other hand, we have the duodenal and appendicular zones of Head, but unfortunately all these cutaneous areas, from the diagnostic viewpoint of duodenal ulcer and chronic appendicitis, offer no serious data on which to rely. While these areas of cutaneous hyperesthesia may not exist in either process under consideration they may be present in certain individuals possessing a hypersensitive nervous system but with absolutely normal abdominal viscera. The impossibility of utilizing Head's points is all the more unfortunate because the diagnostic difficulty is increased in cases of gastroduodenal ptosis. In these cases a pyloric or duodenal pain may easily be attributed to the appendix.

It is evident that an intestinal hemorrhage will fix the diagnosis in favor of duodenal ulcer, but this symptom is frequently wanting. Therefore, occult hemorrhage must be sought for by either Weber's or Meyer's technique, and although their positive reaction confirms the presence of an ulcer, a negative result does not invalidate it. A duodenal ulcer does not bleed constantly, and for this reason the stools should be examined for blood on several successive days.

Finally, radiography, after a bismuth meal, will complete the diagnosis, particularly when, as is usually the case, adhesions exist between the first portion of the duodenum and the liver.

Who Was the Original of Balzac's Country Doctor?

It is said that the great French novelist wrote "Le Médecin de Campagne" in three days and three nights and then took three months to revise the

proofs. The general impression is that the character of Benassis was a mixture of several prototypes. Recently this subject has been agitated anew by Faure, a French litterateur. According to *Le Progrès Médical* of July 13, a letter is in existence—when it came to light is not stated—addressed to the novelist's sister in which it is stated unequivocally that the original of the country doctor was a pupil of the famous Frank, whom he had once consulted for palpitation and suffocative sensations. It is not likely, however, that a man of Balzac's genius followed this prototype slavishly. He was in touch up to the time when this novel was composed with a number of prominent medical men and probably borrowed from more than one of them. Among them was a Dr. Amable Rome and M. Faure regards the latter as the logical prototype for the character of the fictitious doctor. The evidence is wholly internal—the life and activities of Rome showed a decided parallelism with those of Dr. Benassis in the story. Balzac was doubtless well acquainted with the facts of Rome's life. The latter was born in 1781 and was graduated at Paris as a physician in 1808. He settled in Bezançon where at once he began his efforts in behalf of the cretins in that community. Benassis did the same thing in fiction. Later their careers became widely dissimilar, but there are still to be seen some striking parallels. The mode of death and the general mourning of the deceased were in accord, but the simple inscription on the tomb was pure fiction.

Effort Phlebitis.

The subjects of sterile thrombosis and thrombophlebitis have been regarded with more or less scepticism in the past, especially when the notion of phlebitis is added to thrombosis. So-called effort phlebitis, however, was first reported in 1884. A second case did not appear in the literature until 1910, but in 1913 a research by Pellot assembled 11 cases. Murard (*Progrès Médical*, May 25) has found two additional cases and has added one personal case, a grand total of fourteen. This lesion has thus far occurred in one of the upper extremities. The author's observation lacked a blood examination and hence has only limited value. The effort in the case was represented by hard labor for two conservative days and nights, the patient being an electrical engineer in the artillery. The right arm was chiefly used, and after the effort began to swell. The superficial veins were in a varicose state, and the arm was quite powerless. Recovery did not occur until after six or seven weeks and was apparently not complete when the patient was discharged. Lenormant, who wrote on effort phlebitis in 1912, suggests that the thrombosis begins in the small veins as a result of mechanical laceration. In these cases the most careful study fails to show any implication of the general health beyond the natural fatigue due to the extreme effort.

News of the Week.

Cholera in Vienna and Berlin.—Despatches to the Associated Press announce that cholera has been discovered in Vienna and that a number of deaths have resulted. Berlin is also reported to be considerably alarmed over the appearance of cholera. Six deaths are said to have occurred from this disease in the central part of that city.

Influenza Becomes More Widespread.—Reports received by the United States Public Health Service show that on October 3 Spanish influenza had appeared in every State of the Union except five. The situation in the District of Columbia was so acute that Washington has been declared a sanitary zone by the Public Health Service. Upon recommendations from that organization all schools and places of amusement have been closed. The same drastic measures to prevent the spread of the disease have been taken in Philadelphia and many other cities throughout the country. In Chicago the Health Commissioner and the Chief of Police issued orders to every member of the police department directing the arrest of all violators of the spitting ordinance and also of every person found coughing or sneezing without using a handkerchief. The epidemic appears to be on the wane in Boston, but the manufacturing cities in the vicinity are showing an increase in the number of cases of influenza reported. The number of cases reported to the New York Health Department during the week has been fairly large, 2,930 new cases with 212 cases of pneumonia having been reported for the twenty-four hours ending at noon on October 9. The disease has spread throughout the State and at the request of Dr. Hermann M. Biggs, State Health Commissioner, Governor Whitman has placed $50,000 at the disposal of the State Health Department, which will be used in supplying doctors and nurses where they are most needed. In order to lessen the spread of the disease in so far as is possible Health Commissioner Copeland of New York City, after a conference with the heads of his department and representatives of the Chamber of Commerce, the Merchants' Association, and a large number of other organizations, issued a schedule indicating different opening and closing hours for various industries, stores, offices, and factories in order to lessen the congestion of traffic during the rush hours. Smith College has been closed because of the epidemic and the University of Vermont has received permission from the War Department to defer the opening of the college until such time as the epidemic subsides.

Dr. Nathaniel Bowditch Potter has resigned his position as professor of clinical medicine at the College of Physicians and Surgeons (Columbia University), New York City. The resignation is to take effect from June 30, 1918.

Railway Car Toilets.—The Merchants' Association of New York addressed a letter to Hon. William G. McAdoo, Director General of the United States Railroad Administration, asking for the abandonment of the unsanitary practice of discharging the contents of toilets from trains upon the roadbeds of the railways of this country. This reform has been under discussion at various times, but on account of the difficulties of interstate manage-

ment and health regulations no definite progress has been made to protect the public health from this particular danger. Federal control of the railroads has made possible the adoption of a general plan in this direction, and it is to be hoped the advocacy of the reform by so powerful an organization will insure its adoption.

School Lunches Approved.—The Board of Education of New York City has approved the plan to provide luncheons in the public schools. The letter making this announcement states that "Physical health of children is most essential for their complete mental and moral development. The custom of providing them with luncheons at the schools will further very materially so desired an end."

Tuberculosis Survey in Rochester.—The local tuberculosis committee of Rochester is making a survey of that city for the purpose of locating tuberculosis cases and assisting in securing their proper care, and especially for performing such service for discharged soldiers and men rejected on draft examination. It is the present intention of the tuberculosis committee to employ a sufficient number of nurses in addition to the three now on duty, to supply the needs as demonstrated by this survey.

Niagara County Tuberculosis Hospital.—The common council of the city of Niagara Falls has let contracts for the erection of a new brick fireproof administration building for the Niagara Falls Municipal Hospital at a cost of $24,500. It is planned that this building shall be the initial unit of a modern, well equipped hospital.

Venereal Disease Regulations in New York State.—The September *Bulletin* of the New York State Health Department announces that it is incumbent upon each health district, according to Section 343-a, Chapter 264, of the Public Health Law to draw up rules and regulations for the treatment, care, and detention of persons infected with any of the venereal diseases. The State Commissioner of Health is at present preparing a list of suggestions intended to be of service in fulfilling this law. These suggestions will be submitted to the presidents of the various boards of health. Each board of health is requested to frame rules and regulations and submit them for the approval of the Health Commissioner immediately. Niagara Falls has already submitted for approval such rules and regulations. The Bureau of Venereal Diseases of the State Department of Health is cooperating with the Law Enforcement League in the apprehension of venereally infected persons throughout the State who have been a source of infection to drafted men reporting at the various camps. Complaints received by the league are forwarded to the health officer of the district where the exposure is said to have occurred. Specimens for laboratory examination are secured from these persons and submitted to the laboratory of the State Department of Health or to a laboratory approved by the State Health Commissioner. Those persons found infected must immediately be quarantined and treated and later a charge of felony may be preferred against them. The Bureau of Venereal Diseases is preparing a number of pamphlets for public distribution. One of these publications has just come from the press and will be sent to those who request it. Quantities may be secured by committees or organizations who wish them for distribution.

Public Health Nurses Appointed.—Appropriations have been secured for the appointment of public health nurses in the following places: Syracuse, Ilion, Olean, Rensellaer, Dunkirk, Ogdensburg, Tuckahoe, Herkimer, Endicott, Gloversville, Kingston, Hudson, Norwich, Cohoes, Carthage, Greene, Ticonderoga, and the Dutchess County Health Association.

Dr. Ross McPherson of New York City has removed his office to 125 East Thirty-Ninth Street.

Dr. James Murphy has been appointed Health Officer of Anne Arundel County, Maryland.

Opportunity for Clinical Assistant.—The West Side Dispensary and Hospital, New York, announces that there is a vacancy for a clinical assistant in the Urological Clinic. Experience is desirable but not necessary. Further information may be obtained by communicating with Dr. A. L. Wolbarst, 328 West Forty-second Street.

The Ninth Annual Clinical Congress of the American College of Surgeons will meet in this city on October 21-26, under the presidency of Dr. William J. Mayo. The morning and afternoon of each day will be devoted to work in the clinics. On Monday evening the presidential meeting will be held, addresses being given by a number of civil and military surgeons of Europe and the United States, by the chairman of the Committee of Arrangements, Dr. J. Bently Squier, by the retiring president, Dr. John J. Clark of Philadelphia, and by the new president, Dr. William J. Mayo. Tuesday, Wednesday, and Thursday evenings will be devoted to symposia on war surgery, papers being read by many foreign and American military surgeons. On Friday evening will be held the convocation of the College of Surgeons, at which an address on Hospital Standardization will be delivered by John G. Bowman, the president of the college. Dr. William J. Mayo will also deliver the presidential address.

The New York and New England Association of Railway Surgeons will hold its twenty-eighth annual session at the Hotel McAlpin, New York City, on October 21, 1918. An interesting program is offered. Dr. George Chaffee of Little Meadows, Pa., is secretary.

The American Association of Clinical Research will hold its tenth annual meeting at the Hotel McAlpin, New York City, on October 19. A program comprising twenty-two numbers and covering a wide variety of topics has been prepared. The secretary is Dr. James Krauss, 419 Boylston Street, Boston, Mass.

The Tenth Counsellor District of the Arkansas Medical Society, which met at Fort Smith on September 17, elected the following officers: *President*, J. M. Taylor of Forth Smith; *Vice-President*, Dr. H. D. Wood of Fayetteville; *Secretary and Treasurer*, Dr. O. M. Bourland of Van Buren.

Health Instructions Distributed Through Draft Boards.—The United States Public Health Service has issued a circular entitled "Information for Guidance and Assistance of Registrants Disqualified for Active Military Service Because of Physical Defects." This is a four-page leaflet containing

specific information relating to the commoner causes of rejection or deferred classification and makes a strong appeal to those who have been disqualified to have their disabilities corrected as far as possible. The object of this measure is not only to reclaim men for military service but to lessen the burden of illness and disability among those engaged in essential industrial work. It is hoped that this circular will reach far beyond draft boards and be utilized by all agencies interested in improving the public health to instruct the people with regard to their physical deficiencies and the ways and means by which they can be remedied. Over a million copies of the leaflet have been sent out to draft boards for distribution. Specimen copies may be obtained from the United States Public Health Service, Washington, D. C.

Medical Research Laboratory and Clinic at Santa Barbara.—A new building which is to house the "Metabolic Laboratory and Clinic for the Study and Treatment of Nephritis, Gout, and Diabetes" is in process of construction as a part of the Cottage Hospital at Santa Barbara, Cal. The laboratory is the gift of George Owen Knapp and other philanthropic citizens of Santa Barbara and will be one of the most complete plants of its kind in the country. Dr. Nathaniel Bowditch Potter of the Carnegie Institution is the director of the laboratory.

Obituary Notes.—Dr. IRVING HARRY KAUFMAN, a graduate of the University and Bellevue Hospital Medical College, in 1918, died of pneumonia at his home in Brooklyn on October 1.

Dr. MAX MAURICE FLADDEN, a graduate of the University and Bellevue Hospital Medical College, in 1909, died at his home in New York City on September 30.

Dr. EDWARD J. WARE of New York, a graduate of Physicians and Surgeons, in 1885, and a member of the New York Academy of Medicine, died suddenly at his home, on September 29, aged 60 years.

Dr. DAVID L. HAIGHT of New York died, after a brief illness, at the Rockaway Country Club, Cedarhurst, L. I., on September 30, aged 81 years. He was graduated from Yale University in 1860, served as a member of the Sanitary Commission in 1862, and was assistant surgeon at the Douglas Hospital, Washington, D. C., during the remainder of the Civil War.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE THERAPEUTICS OF RESPIRATION—COLD STORAGE —THE AMERICAN RED CROSS IN ENGLAND— STRIKES —DEATH OF PROFESSOR ROBERT SAUNDBY.

LONDON, September 12, 1918.

THE inter-association from a scientific and medical point of view of activities which on their face do not appear to have much in common is well illustrated in the report of the recent Committee of the Privy Council for Scientific and Industrial Research. This committee has considered during the past year recommendations in respect of aid to twenty-one scientific investigations of industrial importance conducted by other bodies, and has appointed in the course of its activities a committee to undertake research into Mine Rescue Apparatus. The Home Office is the State department having control of the inspection of mining industries. The Ministry of Munitions and the authorities of the Royal Air Force were soon seen to be equally interested in the mine rescue apparatus, it having become evident in the course of a long series of respiration experiments that a man's respiratory behavior, when oxygen is administered during manual work, is dependent on his physical condition. Dr. Henry Briggs, who in civil life is at the head of the Mining Department of the Heriot-Watt Technical College at Edinburgh, has devised a method of measuring physical fitness and stamina which was tested during the first half of the present year on a large number of soldiers and miners. The method as devised by Dr. Briggs bore on the selection of men for mine rescue teams, but has since been found to have a new value at the present time by affording a means of ascertaining a man's fitness for the army. The first physical station on Dr. Briggs's system is now being equipped by the War Office in Edinburgh, where it will be run by a military staff attached to the Scottish Command. Thus we see that the work of various civil departments, having totally different objects, is found, through medicine, to have an intimate bearing on the great problem of the moment—the economical use of man-power for military service.

More than a year ago it was represented to the same committee of the Privy Council for Scientific and Industrial Research that a systematic investigation by the Government on all the problems of cold storage should be undertaken with a view to the preservation of food now lost by decay before it can be brought to market. The committee decided to outline a definite method of attacking the problems in question, giving an estimate of the probable cost of the recommended proceedings, when the Board of Agriculture and Fisheries, the Fishery Board for Scotland, the Board of Agriculture for Scotland, the Ministry of Food, and the Food Production Department were all found to be willing assistants. Committees were appointed to carry on experiments on the freezing of fish, to investigate the process of putrefaction, the chemistry of post-mortem change in flesh, and the processes underlying preservation of beef by cold. Similar investigations have been organized in the physiology of fruit and vegetables at low temperatures and into certain diseases which destroy fruit at once. It is certain that the organization of a group of researches of this kind, undertaken with the assistance of an advisory board of distinguished men of science and affairs, will bring about great results, and one of the greatest will be the breaking down of the artificial barriers existing between specialists in one direction and specialists in another. Given common difficulties to attack, the doctor, the physiologist, the physicist and the chemist soon find that however differentiated their techniques their fundamental knowledge is generally common and their plans of campaign capable of united direction. The partial failure of the British fruit crop has been made good over and over again by a colossal harvest,

but none the less dieticians are viewing with regret a probable shortage of apples for winter storing and of plums and other fruits for preserving as jams or by bottling. Medical men have a direct interest in learning what are the possibilities of fruit and vegetable storage, as it is to the doctor that the public looks in dietetic difficulties.

A report of the work of the American Red Cross in Great Britain has just been issued by the Executive Committee, and testifies to the wonderful all-round energy of the organization. Canteens have been opened at ports of arrival at which thousands of men can be served almost without waiting, and similar canteens have been set up along the ordinary routes of travel between the British ports and the point of departure for France. At a large western port and a well known northern port hospitals have been constructed, while an Irish naval base now boasts a large convalescent camp for Americans. In the metropolis the American Red Cross occupies a huge building in the central neighborhood of Hanover Square, and from here the Distributing Service is dealing with an untold number of different requisites—the report shows that on an average over a million articles are handled each month. The Home Communication Service is now housed in Grosvenor Gardens, the splendid mansions overlooking the grounds of Buckingham Palace. A great Red Cross Hospital is also rapidly approaching completion in the Southampton district; this hospital will already shelter upward of 1,000 patients, but its hut accommodation is being extended, and by the beginning of November at least double this number of beds will be available. Difficulties of labor supply do not seem to impede our Western Allies.

It is an open secret to all the world that social life in England has recently been much embarrassed by strikes; it is with deliberation that nothing is said about the effect that industrial unrest may have in affecting our relations with our allies for the conduct of the war. No doubt the occurrence of numerous strikes is a medical symptom of war-strain. This does not imply that none of the strikers have or have had reason on their side, nor does it imply that the authorities have always been free from provocation or judicious in their attitude, but both the governed and the governing classes undoubtedly have frayed nerves through whose pathological working misunderstandings are quickly elevated into disputes and disputes into strikes. It is not often that a strike actually affects the working of the medical profession or the conduct of its duties towards the public, though examples have occurred, notably in Ireland, and in certain industrial centers in England, where the refusal of medical men to accept certain terms and conditions has for a season limited the local medical service. Recently, however, there has been a strike in a lunatic asylum which, in itself, might have had grave consequences and which, if the movement had spread, might have led to serious tragedy. The subordinate personnel of a lunatic asylum in an English county went on strike without warning, leaving the establishment to be conducted as best it could by two doctors and one or two nurses. Those who remained by the ship manned her efficiently, but no one who is acquainted with the medical and administrative working of a lunatic asylum can fail to be aware that whatever they did they must have been compelled to leave much undone that required doing, while their personal responsibility, not to say risk, was such that it cannot be easily contemplated. No particular lesson can be drawn from this strike with regard to the action of the authorities or of the subordinates; the facts will undergo full inquiry and have not as yet been made public in detail. But the mere occurrence points to a frame of mind on one or both sides which must be guarded against in these days of stress, mental anxiety, and material embarrassment. That 120 attendants and a rather larger number of nurses should have suddenly deserted the charge of 2,500 insane patients, some falling under the category of violent, and many, of course, entirely helpless, denotes, to say the least of it, a disregard of responsible humanity which could not have occurred in normal times. It is to be hoped, therefore, that all the attendant circumstances will be thoroughly probed so that the reasons for the situation may become apparent, and a pattern of conduct laid down for the staffs of similar institutions, whereby, while legitimate grievances are redressed, the most miserable victims of pathology are neither seriously jeopardized nor allowed to seriously jeopardize their more fortunate fellows. There is a well-known French comic story describing an émeute in an asylum where the insane inmates rose, overpowered the nurses and attendants, deposed them to the position of patients, assumed the reins of government, and conducted the institution, as far as we remember, with propriety. As a story the situation is droll enough. In real life there is not much in it to provoke laughter.

The death is announced of Professor Robert Saundby, a well known consultant physician, who was for many years professor of medicine in the University of Birmingham. Professor Saundby was a prominent figure on the General Medical Council, and the author of a popular book on medical ethics.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

CONGRESS OF WOMEN WAR WORKERS IN PARIS—SOME FRENCH MINERAL SPRINGS—THE PIANO TRAIN—EXHIBITION OF CHILD WELFARE WORK—RED CROSS ACTIVITIES—ANTI-ALCOHOLIC PROPERTIES OF CYANIMIDE.

PARIS, August 27, 1918.

THE day and hour of the women have come; the war brought them their opportunity and they have shown themselves equal to and worthy of every trust. The great mass meeting of the women war workers of the allied nations has just been held in Paris with representative bodies from America, Great Britain, France, and Belgium. The Y. W. C. A. conference was held at the Hotel Petrograd, where Miss Harriet Taylor of New York, a member of the National Board of the Y. W. C. A., made the opening speech. Miss Caroline Dow, who is at the head of the training school, followed with a short talk, and Mrs. Emerick of California, who is returning to America to speak throughout the country for the Y. W. C. A. drive, also made a few remarks.

The women of the Y. M. C. A. held their conference at the residence of Mrs. Theodore Roosevelt, 39, Rue de Villejust. The American Fund for French Wounded called its members together at the Alcazar, in the Avenue des Champs Elysées. The Red Cross workers met at 4, Place de la Concorde. The English deputation held its meeting at the Lyceum Club, while the French organizations held conferences wherever their work took them. The banquet given at the Hotel Palais d'Orsay in the evening was the great feature of the day. Five hundred women war workers of all nations of the Allies sat down to dinner. Mrs. Robert Woods Bliss presided and spoke in French. Comtesse Hélène Goblet d'Alviella then spoke for Belgium, followed by Mrs. Alfred Lyttleton for England, Miss Maxwell for America, and Mme. Emile Boutroux for France. The band of the Garde Républicaine played throughout the dinner and rendered the national anthem as each of the women spoke for the Allies. The wife of the President of the French Republic held an evening reception for them at the Elysées Palace.

Professor Hayem, whose work upon diseases of the stomach is known worldwide, recently presented before the Academy of Medicine a study upon the action of saline waters in the treatment of dyspepsia. After having described the physiological action of five types of water, representing as their chief components bicarbonate of sodium, sulphate of sodium, chloride of sodium, and chloride of magnesium, and taking as representative types the waters of Vichy, Chatel-Guyon, and Santenay, he entered into their application. In a case of hypersecretion, with dilatation of the stomach and motor insufficiency, he employs the water of Chatel-Guyon, which contains per litre 50 gm. of chloride of sodium and magnesium and 2 gm. of bicarbonate of sodium. He prescribes two glasses of this water before breakfast with one-half hour between, continuing the cure from 25 to 30 days. When the stomach trouble is spasmodic with constipation he adds to the water from 3 to 5 gm. of sulphate of sodium. He has found these saline waters render a great service in many types of dyspepsia. Bourget of Lausanne made them the basis of his treatment which became famous the world over.

One of the duties of the American medical profession at the close of this war will be to aid in turning the trend of travel from the German springs to those of France. I have long had in view a paper to be devoted to a study and description of the famous springs of France and hope to prepare it before long.

At the same meeting Dr. Courtois-Suffit read a report upon delayed and relapsing hemorrhage following wounds of the lung in 34 cases. One case exhibited a hemorrhage 30 months after the wound and was discharged from the army as tuberculous, but later examination disclosed no general symptoms nor were any evidences shown by the *x*-ray, and the sputum contained no bacilli. The report was considered of great interest from a medicolegal standpoint that the delayed hemorrhage and relapsing cases were likely to be wrongfully discharged from military service, as the case cited was distinctly a type of compensatory hemorrhage.

It was a Frenchman, an engine-driver on the Chemin de Fer de l'Est, who gave me the first news of this; and in my innermost heart I cannot wonder at his emotions. "Ecoutez, m'sieur. Without doubt all your Americans are mad; but up by the Verdun sector there are Americans madder than all the rest. Believe me or not, they conduct trains by music." Then he went off into a long harangue about it all, little of what he said being intelligible. As it happened, though, my course bore toward the Verdun sector, and there I had light upon the mystery.

"Là," said a peasant, giving me a direction when I inquired regarding the presence of certain Americans in the district; and his direction pointed to a stretch of standard-gauge track laid with eighty-pound rails of American origin. Presently there hove into view a huge consolidation engine; a "road hog" of the familiar American type. From trucks to tank it was as Yankee as a doughnut, and, what is more, from the cab window leaned forth a figure in jean jumpers that looked as if it had just stepped out of a yard-hutch. By way of greeting the figure gave me a yell and a wave of the hand. The yell was the rebel yell, while the wave of the hand was a veritable "high ball," a signal such as no French trainman ever threw. The light began to dawn then. This was the railroad I'd heard about—one operated by a regiment of United States troops. I went upon that road. I traveled from one end to the other of its hundred miles of trackage; and many things I saw and heard that may not be told of here, for that is military information not to be divulged, but in the course of time I solved the mystery of the piano, and that I may lay clear.

It was a summer's day, sunny and quiet, and it was Sunday. The track, sweeping round the flank of a little hill, entered a heavy cut and was hidden from the view. With four soldiers, all four trainmen of the C., B. & Q., I squatted in the shade of the old French railroad station, or what was left of it since the Boche had dumped his last shells into the place. Then from down the hidden track came the clicketty-click of wheel flanges rolling on the points of the cross-over switches.

The ex-C., B. & Q. trainhand I was talking with said, "Here comes the gas car from H. Q.," and he was going on with his tale when I heard a voice lift itself in song. With the song came the tinkling of a piano. I sat up and took notice.

"Mine eyes have seen the glory of the coming of the Lord:
He is trampling out the vintage where the grapes of wrath are stored;
He hath loosed the fateful lightning of his terrible swift sword:
His truth is marching on."

The piano crashed and other voices broke in with the refrain, fresh, buoyant, youthful voices. Then out of that railroad cut rolled the band of choristers, and such a choir I have never seen before. There came first a gasoline car, such a car as is used by railroad superintendents in the States to inspect the trackage under their care. There were four seats in the car, and the four seats were crowded with the soldiers, all of them singing joyously. Behind the car came a flat, steel-bodied trailer, the kind a contractor uses on railroad work for hauling dirt away from the steam shovels. In the trailer was the piano and seated at the piano was a soldier thumping away at the keys. Other soldiers were

grouped about him, and standing by the instrument was a middle aged man with the brassard of the Y. M. C. A. on his sleeve. Well, I had my mystery explained to me now. This was a soldier's Y. M. C. A. outfit making its regular round up and down the road.

The Red Triangle man told me all about it: "The way it goes, this outfit can't all get to the Y. M. C. A. hut at headquarters, so we go to them. Some of the boys are in places close up to the German lines, and we go to them too. Of course, we have to keep off far enough so that the Huns won't hear us, because if they did we'd have them heaving shells around our ears. But it's great the way the boys take to it. They all turn out when the piano in the trailer comes along." He was right in saying the boys "took to it great." The places they live in have been banged and battered about by the German shells till nothing but ruins remain; and in many places, on account of the shelling, the men in charge of the line have to live in dugouts. In spite of this they manage to operate the road, hanging on through thick and thin. So, indeed, the coming of what they call the "piano train" is a great event. In addition to the piano, the Red Triangle man often takes a moving picture machine on the trailer, and gives the boys a show. Occasionally, too, he has some wandering visitor of prominence to make the boys a talk. One Sunday recently, for example, Judge Tod B. Galloway of Columbus, Ohio, author of the "Gypsy Trail," went out on the car and entertained the boys. It was a quiet day at the front and the judge did not get his head knocked off by a shell. However, there is always a chance of something happening; and one doesn't wonder at the Frenchman's emotion.

Mr. Homer Folks, Director of the Department of Civil Affairs of the American Red Cross in France, has opened an exposition of child welfare work at St. Etienne. In his opening remarks, Mr. Folks said a hundred thousand Americans, through the American Red Cross, presented their greetings to the people of St. Etienne, extended to them their most sincere sympathy, and thanked them for the privilege of being permitted to aid in diminishing the hardships which four years of war had brought upon the children. This Exposition, joint enterprise of the French Government, expressing the national interest in every child of the National League Against Infant Mortality, expressing the philanthropic and volunteered concern for the child welfare of the local authorities and the private agencies at St. Etienne, in children, precious not simply in their irresistible appeal to the emotions, but precious in a more rationalistic sense, in that these young citizens are those who will remake the civilized world when the war is over, carry its burden on their shoulders, and carry out the new policies that must put an end to war. If the lot of this generation has been a hard one—and none has ever been harder—theirs, also, will be extremely difficult. These will need clearness of vision, firmness of purpose, unbounded faith in themselves and their fellows, and unquenchable devotion to the ideals of human betterment. Perhaps it is because we in America recognize how much we owe to France for our social and democratic ideals that we wish to help in every possible way in conserving the childhood of France. We know that France is the home of ideals, the cradle of liberty, always looking to the future, always building a more democratic nation, and therefore, we rely to such an extent upon the part which she must take in the reconstruction of the civilized world after the war.

The exposition if it serves its purpose will accomplish two objects: First, it will attract the attention of everybody to the needs of children and create a general conviction that it is a very easy and simple thing to do, a great deal better for the children than has been done before. Second, it will have set on foot a coordination and rounding out of agencies, public and private, for the care and protection of childhood, addressing themselves seriously and in a comprehensive way to the development of this side of community life as its industrial side has already been developed.

Yesterday the American Red Cross sent seven tons of surgical dressings and five tons of special diet food to the principal evacuation hospital of the American Army in the present offensive. The American Red Cross medical offices, storehouses, pharmacies, and all the services necessary to meet army medical emergencies, operate day and night during the offensive. For example, on Thursday night the chief of the medical section arrived in Paris from the front at 1 A.M. with a list of emergency supplies. He started back at 3.15, having assembled a load of emergency medical supplies containing 50 gallons of alcohol, 2,000 doses of tetanus antitoxin, many surgical instruments, several gross of surgical needles, and operating materials of all kinds. The American Red Cross has added during the present offensive an American Annex of 350 beds, with an American personnel to the American Red Cross hospital at St. Pol, and has enlarged a tent hospital just outside Paris to 300 beds. In addition to these activities the Americans open next Monday in Paris a hospital for skin diseases to be known as the American Red Cross Military Hospital No. 9. This hospital will have an Army personnel, but is equipped by the American Red Cross.

Dr. Langlois has drawn the attention of the French Academy of Medicine to the peculiar anti-alcoholic properties of cyanimide as observed in munition factories, where this important substance is prepared or used. Workers who handle cyanimide, he states, cannot drink even a simple glass of wine without being made seriously ill, the indisposition lasting 12 to 18 hours. On workless days they can drink wine without risk. This new malady is to be further investigated.

146, Avenue des Champs Elysées.

Franco-Spanish National Park in the Pyrenees.—The first steps have been taken toward the establishment of a park in the Pyrenees region which will lie astride of the boundary between France and Spain and be shared equally by both countries. The suggestion for this step appears to have come from the national parks in the United States, Australia, New Zealand and Tasmania, while some of the European countries now have forest reserves.—*La Presse Médicale.*

Progress of Medical Science.

7. Non-Surgical Care of Incompetence of the Ileo-Cecal Valve. John Bryant.

1. Mortality from Organic Diseases of the Heart Among Wage Earners, 1911 to 1916.—Louis L. Dublin points out tnat in the experience of the general population of the expanding registration area in recent years, organic heart disease has ranked first as a cause of death. From 1911 to 1916, inclusive, 75,345 deaths from this cause were recorded among policy-holders of the Metropolitan Life Insurance Company; that is, 11.9 per cent. of the 634,499 deaths from all causes. Though the disease is primarily one of advanced life, the toll is high at the younger adult ages. The death rate is higher among colored persons. It is higher for females than males up to the age period 20 to 24 years, after which the situation is reversed. Comparing the death rate for males in the expanding registration area with that for white insured males, it is found that with exception of the period of early childhood—one to four years—the death rates are much higher for the insured group than for the general population. This is also true in the case of females. The facts of mortality from organic diseases of the heart, as for tuberculosis, show with advancing age the cumulative effect upon the vitality of wage earners of more severe conditions of life and work, and perhaps less favorable hygienic conditions than are found in the general population of the United States. We also find the death rate during the age period from 25 to 45 years very much higher for males than for females in the wage earning element. In the general population, on the other hand, the rates are slightly higher for females. In the industrial department of the Metropolitan Life Insurance Company the rate for 1916 is lower than for 1911 (140.2 as compared with 141.8). In the general population on the other hand, the rate has increased from 140.9 in 1911 to 150.1 per 100,000 in 1916. This increase, however, is largely fictitious, resulting from increased reporting of organic diseases of the heart as cause of death, the inclusion of "endocarditis" and "myocarditis," which prior to 1900 were excluded from the statistics, and so on; and it is significant that in the case of insured wage earners, where such increase would have been expected to show, it is absent.

3. The General Diagnostic Study by the Internist.—Lewellys F. Barker. (See MEDICAL RECORD, February 9, 1918, p. 259.)

5. Syphilis of the Stomach.—Albert F. R. Andresen points out that autopsies on 1,384 known cases of syphilis compiled from the literature revealed but five cases in which histological diagnoses of gastric syphilis were made, and that among 741 of these cases, although 14 had gastrointestinal symptoms, only one was shown to have a luetic lesion of the stomach. The percentage of patients with gastro-intestinal symptoms or lesions of various kinds found to have syphilis is reported as from three-tenths to two. Out of a total of 1,000 patients suffering from all kinds of gastrointestinal symptoms, Andresen found 70, or 7 per cent., had strongly positive Wassermann reactions; of these 70, 26 had demonstrable lesions of the gastrointestinal tract, but in only one case does he feel justified in giving a definite diagnosis of syphilis of the stomach. He calls attention to the fact that a syphilitic may develop an ulcer or a carcinoma as easily as any other individual, and, in the same way, an ulcer patient may acquire syphilis. It is therefore unwise to class gastric ulcer cases with positive Wassermanns as gastric syphilis. In considering the pathology of the disease, Warthin's statement must be borne in mind, that the "common pathology of syphilis is not the gumma, but is a mild chronic interstitial inflammation, leading to parenchymatous atrophy, degeneration and fibrosis." The demonstration of spirochetes by Warthin in these lesions in latent and supposedly cured cases of syphilis has been a surprise to syphilographers. Warthin considers the following changes as characteristic: (1) areas of lymphocyte and plasma cell infiltration; (2) fibroplastic proliferation, frequently of the myxomatous type; (3) vascular proliferations and obliterations. These changes result in localized or diffuse infiltrations of the stomach wall, producing ulcers with marked tendency to perforate, hourglass deformities or pyloric stenosis, or perigastric adhesions; or, in the case of diffuse infiltration, a cirrhosis of the stomach. Gummata occasionally occur. Symptoms of gastric syphilis are not characteristic. In general they depend upon the character and location of the lesion. Loss of weight is a constant symptom, together with more or less severe anemia. Diagnosis is difficulte. Although a strongly positive Wassermann demonstrates the presence of syphilis in some part of the body, it does not establish a diagnosis of gastric syphilis; and, on the other hand, spirochetes have been found in the tissues in cases where the Wassermann reaction was negative. An absolute diagnosis can only be made on the microscopical examination of tissue obtained at operation or necropsy, and even here syphilitic lesions cannot always be distinguished from those that are tuberculous. Nor does gastric analysis aid materially. Since diffuse infiltration of the gastric wall is probably the most usual lesion, achylia is the most common finding, but hyperacidity frequently occurs, especially in pyloric stenosis. positive Wassermann demonstrates the presence of lactic acid, lactic acid bacilli, and a positive Wolff-Junghaus test. In ulcerative cases blood is found in gastric contents and feces. The Roentgen ray indicates the size, location and general character of the lesion. In the therapeutic test it must be remembered that a case of carcinoma may derive temporary benefit from specific treatment. However, if a patient with definite gastric lesion previously resistant to usual treatment, and found to have a strongly positive Wassermann and other evidence of syphilis, improves definitely, with disappearance of lesion, etc., under antiluetic treatment, a diagnosis of syphilis of the stomach may be accepted. Treatment consists of the employment of salvarsan, mercury and the iodides. At first, particularly if salvarsan is given, there may be irritation of the gastric lesion, but as a rule maximum improvement is attained in from four to six weeks. Pyloric or hourglass lesions may clear up completely, but cicatricial stenosis often develops. Patients with perigastric adhesions may be improved, but not cured, while the cirrhotic type of stomach will naturally remain small. The ulcer or gumma cases respond best to treatment. Diet should be soft, soothing and concentrated, with frequent feedings. Dumulcents and alkalies with lavage may be indicated. Rest is important. All foci of infection should be eradicated. Operation should be performed only in the presence of complications, and should be palliative. Treatment results in permanent relief of symptoms in not more than 40 per cent. of cases.

1. Handling of the Venereal Problem in United States Army in the Present Crisis.—William Allen Pusey classifies the methods of attack on venereal diseases as (a) social measures to diminish sexual temptation; (b) education in regard to venereal diseases; (c) prophylactic measures against venereal diseases, and (d) medical care. Social measures may be divided into (1) the repression of prostitution and of the liquor traffic, which go together and are both important factors in the diffusion of venereal diseases, and (2) the provision of proper social surroundings and of opportunities for recreation and diversion. The control of the liquor traffic and of prostitution has called for cooperation between the federal and local authorities; inside cantonments and other Government reservations and within a zone of five miles around each cantonment the federal authorities are supreme, but in other places reliance has been placed in great measure on the local civil authorities, who have realized their responsibilities and made every effort to improve conditions. For the past few years the public interest in measures for the control of these diseases has been steadily growing. Clinics are being established and reorganized all over the country, hospitals are being provided, and from the Atlantic to the Pacific a systematic attack is being made on venereal diseases. Through the Commission on Training Camp Activities the Government is pursuing a policy which aims at creating a class spirit among the men through sports and diversions, much the same as that of a college community. Civil organizations, such as the Y. M. C. A., the Knights of Columbus and the Y. W. C. A., are doing an incalculable work for the soldier both in the cities and in the camps, and the civil population has taken its full share in this work. Among the soldiers the work of education in sexual matters is for the most part under the direction of the War Department Commission on Training Camp Activities and the Social Hygiene Section of the Surgeon-General's office. Instruction is given by lectures, by pamphlets, by exhibits and moving pictures. Information is also distributed to the individual soldier through his company commander, and company officers, both line and medical, give lectures to the men on sexual matters and the dangers of venereal diseases. Though everything is done to discourage prostitution, no attempt at segregation and regulation in the Continental sense has been made, as such measures have not been considered advantageous. As for the medical program, venereal prophylaxis is part of the duty of every regimental infirmary, and is seriously carried out. If a man contracts venereal disease he loses his pay during disability if he has had prophylaxis; if he has not had prophylaxis, however, he is courtmartialed and punished. The loss of pay and the fortnightly inspections are regarded by the Army authorities as important measures in the reduction of disease. The treatment of venereal diseases has been standardized as far as possible, and includes the hospitalization of acute cases. Laboratory facilities are provided in cantonments, and specialists serve as instructors of other medical officers. In addition to this, three schools have been established for the intensive training of men in this work. Pusey points out that the present policy of the United States Army is not new: it is one that has been developed by the medical department, and which resulted in a reduction of venereal diseases by 50 per cent. from 1911, when the rate was 164 per thousand, to 1913, when it had dropped to 86 per thousand. Mobilization on the Mexican border resulted in an increase of cases, and the rate in 1916 was 91.4. In September, 1917, with the second week of mobilization, the rate shot up to 367 per thousand. In the National Guard at that time the rate was 150, and in the Regular Army 80. (It should be remembered that the high rate for September, 1917, in the National Army includes all cases of venereal disease, old as well as new.) The contrast between the figures in the National Army and the National Guard is interesting, for it affords a comparison of the prevalence of venereal disease in the National Guard with its relatively lax discipline with that in civil life. From the time of mobilization the rate rapidly declined, and for the whole Army for the year 1917 it was only 88. Among the American forces in France, from November, 1917, to June, 1918, for only two weeks has the venereal rate reached 90, the figures from December 21 being 75, 57, 74, 58, 52, 55, 44 and 48.

1. The Lumleian Lectures on Celiac Disease.—G. F. Still takes up in his third lecture the treatment of celiac disease. He commences his discussion by pointing out that until celiac disease has been traced to one specific cause, or the grouping called by this name has been shown to be divisible into specific entities, treatment must be more or less symptomatic and empirical. Drugs, while not entirely impotent in the treatment of celiac disease, have a very limited scope, and chief reliance is to be placed on scrupulous care in dieting. One of the outstanding features of the disease is failure of fat assimilation, and therefore the element in the food which requires most consideration is the fat. Moreover, the form of fat which seems most obnoxious to children suffering from this disease is the fat of cow's milk, and this is a point upon which the greatest emphasis should be laid, for the tendency is to put such a case upon milk, whereas nothing is more likely to retard recovery. Experience has shown that the best results are to be obtained by reducing the fats to a minimum. This may be done by replacing fresh milk by a dried milk containing only a small proportion of milk fat, or by asses' milk, which usually contains not more than 1 per cent. of fat. These children appear to have a special intolerance for the fat of cow's milk; they do excellently on human milk, which contains a larger proportion of fat, and are unable to tolerate cow's milk given in the form of whey in which the fat has been reduced to not more than 1 per cent. Fats derived from other sources are also badly tolerated, cod-liver oil, oil obtained from the soya bean, and even that present in the yolk of egg, all aggravate the symptoms, the intolerance manifesting itself by increased looseness and offensiveness of the stools. Starches are better tolerated than fats, but bread is particularly liable to aggravate symptoms. Sugar is allowable only in small quantity. "Nurso" and "Malac"

biscuits, "Ravenlenta" prepared from lentils, chicken or veal broth, and sweet jellies, rice boiled in water for three or four hours, and in some cases eggs may be given. Such a diet is definitely scorbutic, and as a rule fruit juices and green vegetables increase the looseness of bowels; sometimes grape-juice is tolerated. Dr. Gee mentions a child who did well on a quart of Dutch mussels daily, but relapsed when the mussel season was over, and next season could not be prevailed upon to take them. Marked success has been obtained in some cases by a "fat-free" diet consisting of rusks, Robb's biscuits, jellies, chicken and veal broth, rice boiled in water, ravenlenta, mashed potato, pounded chicken or fish, barley water or weak tea with sugar. In this the potato is an effective antiscorbutic. Contrary to what might have been expected, rickets is strikingly absent in cases of celiac disease; this is true also when fat has been eliminated from the diet. From the point of view of general nutrition it is desirable that fat should be absorbed if possible. There is evidence that it can be absorbed if injected into the subcutaneous tissues, a mode of administration obviously undesirable for children. Still has attempted to treat cases by inunction, but the results have been inconclusive. The administration of digestive extracts has likewise been tried, but without result. Calomel seems to aggravate the bowel symptoms. Most of the astringents, both vegetable and mineral, have proved useless; castor oil in small doses given three times daily usually brings about some improvement, and silver nitrate has been of use in certain cases. Chromo-santonin may prove of value, but further observations on its worth in celiac disease are required. Vaccines have been of only temporary advantage, and in some cases have produced no effect at all. In view of the arrest of growth in these cases, it has been thought that one or other of the internal secretions might be deficient. In three cases the author administered thyroid, but without improvement. In one case increase in height followed the use of polyglandin, but the child's power of assimilation had also improved so much that it cannot be said that growth was the result of the drug. It is, of course, conceivable that the general interference with nutrition caused by failure of fat absorption may affect the internal secretions and therefore the growth. Professor Still believes that with due care in dieting—remembering the intolerance for fat—it is possible to obtain marked improvement in these cases, and that a large proportion of them can be coaxed back to health and even to an average power of assimilation after many months or years of patient perseverance with a very restricted diet.

1. A Clinical Lecture on Ischemic Myositis.—Sir James Purves Stewart defines ischemic myositis as an affection of a muscle, or part of a muscle, resulting from local limitation of its blood supply. Its causation, in times of peace, is usually the too tight application of bandages or splints over a fractured forearm or elbow; in war it is obstruction of the main artery of the limb by ligature; or, in some cases, it may be due to spontaneous obstruction of the main artery from embolism or thrombosis. As to treatment, in ischemic myositis due to tight bandaging and splinting, usually limited to the flexors of the wrist and fingers, artificial lengthening of the flexor tendons at the wrist has been tried. The disadvantages of this operation are the extensive dissection required and the prolonged after-treatment of the wound. A simpler operation is one which shortens the bones of the forearm by excising an inch or more of both radius and ulna, so as to allow of the fingers being placed in a position of extension and even slightly hyperextended. The patient then has a shorter forearm but a more useful hand. The drawback to this procedure is the tendency to the formation of still more scar tissue by operating on an already sclerosed limb. It is therefore better to attack this class of case, as recommended by Sir Robert Jones, by means of careful and systematic stretching of shortened tissues. The wrist is first passively flexed by an assistant, allowing the fingers to extend. Small metal finger splints are fixed to each digit by adhesive strapping, leaving the pulps of finger tips exposed. Over these digital splints, either at the first sitting or a day or two later, is fixed a flat palmar splint, to keep the phalanges and metacarpals in line. At intervals of two or three days the wrist is gradually extended, a few degrees at a time, being fixed in its turn to a series of suitably angled splints, until wrist and hand are in a position of extreme dorsiflexion. The wasted finger pulps begin to fill up, and the power of voluntary dorsiflexion gradually reappears. Massage, hot douches and whirlpool baths aid in softening and stretching the affected muscles, and may be supplemented by local hypodermic injections of thiosinamine. A considerable degree of recovery can thus be obtained. In cases due to arterial obstruction, balneological measures, massage and passive movements may be of value, but if a muscle or group of muscles has been practically reduced to fibrous tissue, little can be expected in the way of recovery of voluntary motor power.

3. Suggestions for the Treatment of Septic Wounds.—Captain Frederick W. Robinson analyzes 1,000 cases which came under his observation. All were in a more or less convalescent stage; 75 were neurasthenic, while 505 were the subjects of wounds, 249 suffering from disability owing to pain, limited movements and deformity. Disability was entirely due to scar defects, the scars being distinguished by their multiplicity and by the large number that were adherent, irregular, and infiltrated—the result of early infection of wounds and the impossibility of applying appropriate treatment at the early stage. The prevalence of intractable neuralgias Captain Robinson believes to be due in great measure to the large number of these adherent scars. As a result of his experience in the South African war, he has invented an instrument by means of which a wound may be elevated and immobilized. This instrument, which can be made on the smallest scale and adapted to the finest surgical needles, consists of two slender looped splints, a system of wormed needles with detachable points and nuts which travel on the needles. In this way the splints are made to approximate to each other and so compress the intervening tissues. An immobility is thus obtained quickly and easily, and is far more perfect than that obtained by splints. There is no traction on any part of the area included within the needles, and the edges of the wound are flaccid and tend to fall together. In the compressed area the circulation is controlled and easily regulated; it is more equable and protected from reflex vasomotor impressions. The physiological engorgement ensures a flooding of the basal areas with bactericidal serum and the infected interstices and lacunæ are reached. The base of the wound is rendered more superficial and more adaptable for any surgical toilet

that may be necessary, and the lymphatic spaces are opened out and easily reached. Where there are wound diverticula at the base the procedure is modified as follows: Small portions of tissue are pinched up and transfixed and retained by small splints; an encircling ligature is thrown round the wound, passing beneath the needles, and drawn tightly. The distance between the wound margin and the ligature must always be greater than the deepest part of the wound. During the progress of healing, the perfect immobility of the compressed area obtained by the use of this instrument gives the best possible condition for the building up of healthy scar tissue. Robinson points out that the avoidance of anything that tends to depreciate the vitality of the growing cells is of equal importance, and here the nature of the dressing must be considered. Any dressing that is to be applied to a granulating surface must be absorbent, absorbable, and perforated. Many years ago the author invented a dressing from cancellous tissue of bone which is both absorbent and absorbable. It fails, however, in freely secreting wounds, and does not provide sufficiently for drainage. He believes, however, that if modified, the matrix of bone tissue will ultimately form a basis for dressings. For the development of perfect scar tissue he points out that absolute rest in the healing zone is essential. Contractility in a scar presupposes undue traction in the wound, and it is the presence of this quality in a scar that is responsible for so many disabling conditions that remain after healing.

Berliner klinische Wochenschrift.

July 29, 1918.

On Lymphogranulomatosis.—F. Kraus and von Lubarsch publish two papers in the form of reports followed by a prolonged discussion. Some of the speakers have noticed a real increase of cases of this disease since the beginning of the war. As to the relationship between lymphogranulomatosis and tuberculosis the various speakers consider it as generally doubtful, even in the attenuated forms which gave rise to this supposition. Umber refers to certain symptoms of the disease which we think are new, namely, a dryness and pigmentation of the skin with violent pruritus.

Some New Procedures in Bacteriological and Serological Examination of Influenza.—W. Leventhal describes a new culture medium which facilitates the diagnosis of the grippe, namely, nutritive agar-agar at 2 to 3 per cent. liquefied at 70° C. and then cooled. To this is added defibrinated blood at the ratio of one drop to each c.c. of agar. Then boil lightly three times, allowing it to cool each time. Decant or filter and then pour it on to plated and inclined tubes. The aspect of this medium is that of pure agar but chemical reaction detects the presence of hemoglobin. Colonies of Pfeiffer's bacillus develop in the form of colorless droplets in large number. They may be used for agglutinating sero-reactions which are positive at 1/25 up to 1/100. Leventhal has also observed that this culture medium is very favorable for the growth of the Koch-Weeks bacillus (conjunctivitis).

Münchener medizinische Wochenschrift.

July 23, 1918.

The Relation of Nephritis to Lipoid Metabolism.—W. Kollert and A. Finger have found that the majority of nephritic subjects offer a more or less cloudy blood-serum (pseudochylous) during the period when their urine contains lipoïdes. The only exception to this rule is nephritis from sublimate poisoning, the blood-serum remaining perfectly clear during the entire evolution of the process. The writers believe that the hypercholesterinemia of the nephritides is due to the concomitant hepatic changes which prevent the physiological elimination of the lipoïdes. They have been able to detect a hypercholesterinemia in all nephritides accompanied by an albuminuric retinitis and they likewise affirm that this condition of the blood is absolutely necessary for the production of this ocular complication.

Is Radical Excision of the Wound in Comminuted Fracture from Bullets Proper?—L. Böhler is absolutely adverse to the present tendency of excising wounds of warfare extensively and the prophylactic removal of bone fragments. He even goes so far as to deny the propriety of this procedure. This extreme conservative opinion is quite legitimate in Böhler's opinion from the excellent results he personally has obtained from conservative treatment. He likewise maintains that free incision and resection of the bone fragments favors the production of pseudarthroses. Therefore, he proceeds with the same prudence in wounds of the joints and he is of the opinion that wounds of the soft structures alone may be treated by excision of tissues whose vitality is compromised.

Deutsche medizinische Wochenschrift.

July 25, 1918.

On Regeneration of Joints.—E. Payr has collected various data relating to regeneration of traumatic lesions and dislocations of joints. The genesis of fissure of a joint would seem to be more particularly related to the movement of the various parts composing the joint, the shape and extent of the fissure being decided by the muscular movements and the point of insertion of the muscles. From the viewpoint of development, Payr recalls that the articular capsule of many vertebrates possesses a layer of cartilage over its entire extent, the synovial membrane thus representing a modified type of cartilage. The synovial fluid must not be regarded as an inert liquid having a passive rôle, but rather as a product of a processus of wear of both cartilage and synovial membrane, and it plays an active part in the nutrition of the joint, and, perhaps, even in histogenesis. From the viewpoint of regeneration it is the most inert tissue of the body, cicatrization of traumatic injuries to it being always insufficient when not aided by the intervention of the perichondral and subchondral connective tissue structures. Other than for the cartilage, joints are among the structures giving rise to the most perfect regeneration, and the writer supposes this to be due to the relative simplicity in function and the slightly advanced differentiation of the parts making up a joint. Repair is more complete in surfaces undergoing reciprocal friction than in the complimentary surfaces of the joint, from which it results that glenoid joints undergo better repair than hinge joints. The joint capsule possesses an astonishing regenerative faculty. This fact is illustrated by its rapid repair after extensive excision as is practised, for instance, in chronic arthritis with a fluid collection (lymphatic drainage of the joint). As to the joint ligaments, their possibility of regeneration has been little studied, but as a feeling of insecurity exists in this respect, it has given rise to aponeurotic plastic operations, sutures, etc.

La Presse Médicale.

June 24, 1918.

The Sign of Vitropression.—Nicolas, Favre and Saleur describe this little known diagnostic sign, which is regarded in some quarters as classical for the dermatologist. Perhaps it would be more correct to state that this sign is not known by that name, or indeed by any name, for the sign of vitropressure is nothing but the anemia produced by pressing on the skin with a slip of transparent glass. By thus eliminating the redness due to mere hyperemia, we can analyze other sources of discoloration due to different causes. In lupus the use of the glass slip is indeed classical, for if we force out the blood from a given area the lupus lesion is seen to present a characteristic shade of color which has often been compared by the English and Americans to apple sauce and by the French to apricot preserves. More accurately, the hue is reddish yellow, and moreover it is somewhat translucent. A refinement of this test is the anointing of the skin to be examined with vaseline, the latter rendering the scales of the lupus placques somewhat more translucent. In a case quoted the patient presented a large area of disease over one of the scapulæ. There were infiltration and ulceration. In some of the outlying discreet papules of the disease, the act of vitropression gave the typical apple-sauce shade of color. In the absence of this sign the first or temporary diagnosis would doubtless have been

syphilis, for the very good reason that the man was a syphilitic and presented undoubted lesions of the disease elsewhere. He even presented typical syphilitic lesions in the skin of the thigh. A biopsy of the lupus-like lesion revealed histological evidences of tuberculosis. From the practical viewpoint the case could hardly have been important, for all of the lesions, including the supposed tuberculide, disappeared under mixed treatment. A second case of the same type in which there was a lupus-like lesion of the face gave under vitropression the lupus coloration—a variety known to experts as the barley-sugar color. This patient presented no evidence of syphilis, but his Wassermann was positive. This patient also recovered under mixed treatment. The author adds a number of similar cases. The question must now arise whether these lesions were really tuberculous or were syphilitic. The apple-sauce color and the histological picture of tuberculosis are not in themselves enough for a diagnosis of the latter. To make certain of this diagnosis we should have to discover the bacillus or obtain a positive tuberculin reaction. The authors did not go to the trouble of settling this question, doubtless because convinced that the cases were frankly syphilitic. It is evident that the apple-sauce coloration under glass has no real final significance in the diagnosis of lupus.

Norsk Magazin for Laegevidenskaben.

June, 1918.

Retronasal Tumors.—Leegaard tabulates the records of 14 cases of retronasal tumors treated by him durthe past four years. In nearly all of these cases the growths were extirpated by Denker's operation, the only exception being a recurrence. Two subjects died as a result of the intervention, one apparently from shock and the other from the results of persistent postoperative hemorrhages. Ten cases were cured permanently, and one is marked "doubtful" recovery. The remaining case is an unoperated recurrence. The total number of recurrences was three, of which two were cured by second operation. The patients were with one exception adolescents—boys of from 13 to 20 years of age; the exception was a boy of six years. The absence of any girls from this series may have been due to the character of the operation, which excluded their sex on account of the resulting disfigurement. The microscopic diagnosis appears to have had no connection with the prognosis. The cases marked sarcoma recovered, while the relapsing and fatal cases were not sarcomatous. The narcosis used was general in all but five cases, chloroform being the anesthetic; in the five exceptions Kuehn's intubation was substituted. The shock death occurred under the latter, morphine and ether having been the anesthetics.

Poisoning from Hexamethylene Tetramine.—Ustvedt relates the case of a man of 31 who had been attacked by poliomyelitis. During the next two days the drug was pushed until 12 grams had been taken. The patient was urinating freely at first, but the diuresis was suddenly checked and blood appeared in the urine along with much backache. There was no headache or vomiting, and the urine increased again and cleared up somewhat. The hematuria lasted five days in all. The 12 grams of the drug had been ingested within 36 hours, equal to a five-grain dose hourly for that period. Such cases are not so rare, and are not usually classed as drug intoxication, but rather as simple overaction.

Correspondenz-Blatt für Schweizer Aerzte.

June 15, 1918.

Does Achylia Gastrica Predispose to Cancer of the Stomach?—Hofmann recalls that the discovery of absence of free HCl in cancer of the stomach goes back to 1879. Its importance was at first somewhat exaggerated, for it was believed that this defect was pathognomonic of cancer. The condition known as achylia gastrica was not recognized until long after. However the symptom of negative Congo red gastric juice is one of the most valuable in clinical medicine, and is present in at least 80 per cent. of cases of gastric cancer. The rationale of the symptom is still to seek. The various hypotheses sound far fetched. Significant is the fact that diminished free HCl is found in some cases of cancer in localities not near the stomach. After extirpation of the cancer from the organ the free acid does not reappear in the gastric juice. This fact seems to antagonize Riegel's toxin theory, which might otherwise prove to be the most plausible among the various speculations. Even when the neoplasm is very small there may be a high degree of defect of free acid. The highest degree of low acid is found in cancer of the fundus and conversely one may not infrequently find free acid in cancer of the pylorus. But the twenty per-cent. of negative results furnish a considerable handicap to understanding the relation of acid to cancer, while in the opposite direction we find anacidity in such unlike conditions as pernicious anemia and cholelithiasis, in diabetes and consumption, in migraine and syphilis. We also find lowered acidity in various other affections, as arteriosclerosis and nephritis. As a result of all of these finds we have to imagine a general condition—achylia gastrica—which occurs in a great variety of conditions of which cancer of the stomach is merely one. In addition to the preceding, anacidity or hypoacidity is found in a considerable per cent. of local affections of the stomach exclusive of carcinoma. The notion of a general affection, achylia gastrica, was introduced into clinical medicine by Einhorn in 1892. The great frequency of achylia in cancer must lead to the query, "Might not the former be a predisposing factor in the latter's evolution?" It is most certain that when we find an achylic in the clinic we begin to fear a future cancer and we keep such a patient under strict control, especially if we look forward to the possibility of early surgical intervention. There is even a forensic side to the question, as appears from the following case: A woman of 42 was found to have a persistent achylia which her medical attendant thought lightly of. In an application for life insurance she did not think it necessary to mention it and the policy was duly issued. Nine months later her health failed and she repaired to a sanatorium, where Schorlemmer made a diagnosis of cancer of the fundus. After her death the insurance company refused to pay the claim by reason of the obvious deception practised on them. Schorlemmer in his testimony appeared to take the woman's side of the case, that her health was not involved at the time of the examination and that no wilful deception was practised. The mere fact of simple achylia is certainly no evidence of the likelihood of cancer, although in theory there is certainly a plausible connection between the two. There is reason to believe that at the outset the irritation of a beginning cancer along with the interference with digestion and the consequences of indigestion would rather tend to set up a gastritis with increased acidity; this condition might in turn be followed by the opposite state of anacidity. Certainly the cases which develop on an ulcer basis must often pass through a period of hyperchlorhydria. There is another argument remaining for consideration. It is often quite overlooked that in the elderly—the people of cancer age—there is often a physiological decrease in the amount of free acid in the stomach. Hence the alleged frequent association of hypoacidity with certain of the diseases of old age is often no more than a coincidence. It is also pointed out that achylia is an eminently chronic condition which may often be followed up in the clinic for many years and that these chronic cases do not become cancerous. Two authors have previously worked out the problem with a relatively large clinical material, and have found that a small percentage of achylics do become cancerous, but the percentage was far too small to possess any significance. The author now introduces his own large figures and shows that of 340 achylics only 4 actually became cancerous during the observation period (4 to 16 years).

Chaulmoogra Oil in Leprosy.—Stévenel claims that since this substance undoubtedly has power over leprosy we are bound to use it intensively by intravenous injection. This route is in fact inevitable for the drug cannot be pushed by the mouth without the development of intolerance. The author makes a 5 per cent. emulsion with distilled water and has to report encouraging results.—*Bulletin de la Société de Pathologie Exotique.*

Book Reviews.

On the Fringe of the Great Fight. By Colonel George G. Nasmith, C.M.G. Price, $1.50. New York: George H. Doran Company, 1918.

This is one of the most interesting books of the war, for it treats of a phase of which little has been said, of the life, military and civilian, immediately behind the front. It is written by a sanitary officer of the Canadian forces who, while not on the front line, yet had an opportunity of seeing a great deal of the fighting as well as of the transport, cantonment, sanitary, and other work preliminary and auxiliary thereto. He saw and describes the first gas attack near Ypres, and he devised the mask with its antidotal medication to protect against the chlorine fumes. He saw much else of interest in the life of the troops and of the civilian population immediately behind the front and describes it in an easy narrative style that pictures it all most clearly to the reader. The description of the beauty of springtime in England and of the dreariness and misery of life on Salisbury Plain during the tiresome period of training is most vivid. One might think the book would be especially attractive only to the medical man, but this is not quite correct, for there is nothing technical about it, and the chapters on the "Medical Organization of the British Army," "Keeping the British Soldier Fit," and "Laboratory Work in the Field" will be just as interesting to the layman as to the civilian physician.

The Treatment of Syphilis. A Critical Review by L. W. Harrison, D.S.O., M.B., Ch.B., Lt.-Col. R.A.M.C., Lecturer in Venereal Diseases and Officer-in-Charge Military Hospital, Rochester Row. Price, $1.00. Oxford: Clarendon Press, 1917.

The greater part of this work deals with arsenicals in the treatment of syphilis. It is an excellent digest of the scientific work done in this branch of medicine, especially in Europe. The author quotes many opinions which give light on some of the puzzling intricacies of physiological chemistry following the administration of arsenicals. He likewise deserves our thanks for excerpting opinions frankly condemning certain preparations vaunted by their manufacturers.

The Elements of the Science of Nutrition. By Graham Lusk, Ph.D., Sc.D., F.R.S. (Edin.), Professor of Physiology at Cornell University Medical College, New York City. Third Edition, Reset. Price, $4.50. Philadelphia and London: W. B. Saunders Company, 1917.

The subject of nutrition is of the first importance, and has been recognized as such for some time; but it is only recently that it has been regarded as a science. The able discussion of the subject by Professor Lusk will appeal to physiologists, laboratory workers on problems of nutrition, dietitians and practising physicians. The aim of the book is "to review the scientific substratum upon which rests the present-day knowledge of nutrition both in health and disease." The work begins with an important introductory chapter; this is followed by a description of the Atwater-Rosa Respiration Calorimeter; then follow chapters on starvation; regulation of temperature; the influence of protein food, of fat, and of carbohydrate; the influence of mechanical work on metabolism; normal diet and the nutrient value of various materials used as foods; the food requirements during the period of growth; metabolism in anemia, at high altitudes, in myxedema, in exophthalmic goiter, in diabetes, in phosphorus poisoning, in nephritis, in cardiac disease, in other cases involving acidosis, in fever; purin metabolism, gout; and the influence of certain drugs upon metabolism. The first edition of this book appeared about twelve years ago, and was half the size of the present volume; in the preface to this new edition the author states that he has no intention of again revising this book. This, then, may be a suitable place in which to record the value of Professor Lusk's work and the debt of gratitude owed to him by students, practitioners, and scientific workers. It is to be hoped that writers on dietetics will make use of the contents of this volume; for some of the available works on dietetics are not up to the standard of Professor Lusk's book.

A Treatise on Cystoscopy and Urethroscopy. By Dr. Georges Luys, Former Interne, Hospitals of Paris; Former Assistant in the Department of Urinary Diseases at the Lariboisiere Hospital; Laureate of the Faculty of the Academy of Medicine. Translated and Edited with Additions by Abr. L. Wolbarst, M.D., New York, Cystoscopist, Beth Israel Hospital; Consulting Urologist, Central Islip and Manhattan State Hospitals; Genito-Urinary Surgeon, West Side German Dispensary and Hospital; Author of "Gonorrhea in the Male," etc. With 217 Figures in the Text and 24 Chromotypographic Plates Outside the Text, Including 76 Drawings from Original Water Colors. Price, $7.50. St. Louis: C. V. Mosby Company, 1918.

The review of the parent volume of this work appeared in these columns October 24, 1914 (Vol. 86, No. 17, page 734). The translator gives as reasons for the English edition, first, to bring Luys' message to English readers; second, "to express in concrete form the love and affection which the translator feels for France." He is indeed to be congratulated for his proficiency in the lyric language of Corneille since in no paragraph, sentence, or phrase has he been traitorous to Luys.

The editor has written sixteen bracketed paragraphs aggregating twelve hundred words inserted through the chapters. Braasch's contribution on "Direct Cystoscopy" covers two pages. He advocates direct vision with lens instruments and water dilatation of the bladder. Winfield Ayres (page 356) submits his conclusions on the treatment of vesical cancer by radium and finds that this agent is less effective in bladder cancer than in neoplasms in other parts of the body.

The figures and plates are identical with those of the original work and from a mechanical viewpoint the book is all that could be desired.

Modern Operative Bone Surgery with Special Reference to the Treatment of Fractures. By Charles George Geiger, M.D. Price, $3. Philadelphia: F. A. Davis Company, 1918.

The preface tells us that the author believed there was a great demand for a "comprehensive, yet abridged, book on 'plastic bone surgery' suitable for the busy surgeon," but he found this "a difficult task, because there is no similar work on the subject published up to the present time" and "all previous publications on bone surgery are largely composed of reports of cases."

One having a fair acquaintance with this subject would deduce from these quotations that the author could not be very familiar with the literature, for books previously published do cover the subject thoroughly and certainly are far from being "largely composed of reports of cases." And yet, as we read this book, we soon gained the impression that the author must have been a rather close student of at least one of the older and quite adequate books, for many of the "author's methods" reminded us most forcibly of Albee's, and many of his instruments and other mechanical devices reminded us again of Albee, of Murphy, of Lowman, and of Hawley. That our impression of the author's cognizance of Albee's book, at least, was correct was proved when we found not only sentences but even paragraphs taken bodily from Albee's book on "Bone-Graft Surgery," sometimes with slight changes in wording here and there, but rarely, if ever, distinguished by quotation marks as having been borrowed from some other author's work.

It is our impression that this book is a rather good compilation, "comprehensive, yet abridged," on bone-graft surgery.

V. Magnan. Sa Vie et Son Œuvre (1835-1916). Par le Dr. Paul Sérieux, Médecin des Asiles d'Aliénés. Paris: Masson et Cie, 1918.

This biography of the eminent French alienist comprising 168 pages is reprinted from articles which appeared originally in the *Annales Médico-psychologiques*. The effort is not divided into chapters and is merely a running account, but an interesting one, of the subject's personal and professional activities and productions. It contains a reproduction of a medallion which was struck off in 1908 in commemoration of Magnan's retirement from his active labors at the age of seventy-five.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Fifty-Second Annual Meeting, Held at Spring Lake, N. J., June 25 and 26, 1918.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page* 609.)

THE VICE-PRESIDENT, DR. THOMAS W. HARVEY OF ORANGE, IN THE CHAIR.

Address of the Vice-President.—Dr. THOMAS W. HARVEY of Orange delivered this address. He said, in part, that the officers of the society had been hoping all along that their president, Colonel William G. Shauffler, would arrive at the eleventh hour to take charge of the meeting. The exigencies of the service had prevented his coming. They had also hoped that if Colonel Schauffler did not come his address would arrive. The delay was not the fault of their president, but was probably due to the fact that all public addresses made by men in the service had first to be viséd by the Surgeon-General's office. Under these conditions Dr. Harvey said he had not prepared a formal address. He felt sure that all took pride in the work their president was doing. He had always been an active man of affairs, in the State Sanitary Association, in the work of the State Board of Education, and in the National Guard. They had always known that it was good policy to follow where he should lead, and that he could always be found on the side of sanity in any progressive work. He had now the good fortune to be serving his country when so many were fretting at the reins. Their society, dating back as it did well into Colonial times, had passed through all the wars of the Republic. Its records showed that before the Revolutionary War broke out it had twenty-five members. New Jersey was the battle ground of the Revolution and naturally all activities save those of war were at a standstill and this society held no meetings and made no reports for six years. During the Civil War the meetings of the society went on as usual, but large numbers of its members enlisted in the service and many never returned. When the present war began our medical men in large numbers immediately responded to the call to arms, sacrificing, as ever, more than any other class of men in their efforts to relieve suffering and to prolong life. The men of their State had responded well to the call and many more were willing to go. There were some 3200 doctors in New Jersey, 525 were already commissioned, and in this second call their quota was 100. There could be little doubt that the required number would come forward and many more. Over 17 per cent. of the New Jersey doctors had accepted commissions, while the average for the country at large was 13.7 per cent. Already two members of their society had made the great sacrifice and it was fitting that their names should be mentioned. They were Dr. Archibald T. Graham and Dr. James E. Griswold. To the older men had come the call to serve in many ways. To those who had served on exemption boards and medical advisory councils had been given the opportunity to do their bit, and certainly more interesting work would be hard to find. It was very gratifying to be told by their fellow member, Dr. Costill, that of the men sent up to the cantonments by their various boards not more than 3 per cent. had been rejected. Over 500 of their doctors had been serving on the various boards of the State. Now other opportunities were about to be offered to those of them who could not be soldiers. It seemed unnecessary to call on the members to respond. Let all who could place themselves at the disposal of the Government for any work for which they had a capacity. The work of the world to-day was war, and it was a war that would end only when we had firmly established the principle that the will of no one man nor group of men could exploit the bodies and minds of other men for their selfish ambitions. Medicine had always held out this idea to its followers. All their efforts, all their lives, were devoted to the conservation of life and the relief of suffering. Any ideal that could add to suffering was abhorrent. To-day the issue was fairly engaged. America was on that side of this war that aimed to realize such ideals. We, as a people, were united to-day as never before for this purpose and we, as medical men, would be false to our training and to the ideals of our art if we did not in every way and at any cost devote our knowledge, our talents, and our lives to further every effort that our country was making. To-day there was no middle ground—it was either America or destruction.

Oration on Surgery.—Dr. GEORGE D. STEWART of New York delivered this address, in which he said, in part, he had elected to take a rapid and general survey of certain parts of the field of surgery rather than to attempt to go into detail on any specific topic. Although what he had to say was supposed to concern surgery and surgical practice, he wished to be understood as speaking in some degree for the whole profession and to enter a protest against the assumption that all medicine and medical practice in war was surgical. The relations between medicine and surgery had been complex enough and too often diverging without encouraging any further sundering at this juncture. One factor in America, at least, which tended to make schism between these two branches of an honorable profession was our interne system which, at the end of two years, turned out men who had done a few operations which the patients had survived and who, in consequence, believed themselves to be capable and fully equipped surgeons. To prevent these premature surgical births he had recommended one year hospital for all graduates, promotion within the ranks at the end of that time for merit and aptitude and still further promotion at the end of eighteen months or two years to the position of residents (surgeon or physician) with pay. Dr. Stewart then spoke of how war generally had affected the study and practice of medicine. He said that for a long time it had been his opinion that wars did not teach much in the way of medicine and surgery, but he had changed to the feeling that in some departments of our science war afforded the largest and unfortunately the most sorrowful of experimental laboratories—laboratories that would not be possible under any other conditions of civilization.

Dr. Stewart said that we might group the methods of wound treatment now in use as (1) the antiseptic, (2) the vaccine and sera and physiological, and (3) the dissection of devitalized tissue. Under the antiseptic method he considered the Carrel-Dakin method, the bipp method (bipp being bismuth subnitrate or carbonate, one part; iodoform, two parts; paraffin in quantity sufficient to make a soft paste), brilliant green, and methylene blue. Antiseptics constituted a revival and improvement of Lister's work in the prevention of infection, by means of modern highly efficient antiseptics combined with an adequate technique. Whether or not the Carrel-Dakin method would maintain itself in its original form or be utilized under the form of dichloramine-T it was impossible to say, but some entertained the feeling that, after all, the antiseptic agent might turn out not to be the essential part of this treatment, and that the secret of the success which had lately attended this treatment in contrast to the acknowledged failure of surgery in the first year of the war was due, not so much to any one of the numerous antiseptics now in vogue, as to the thoroughness with which the contaminated areas were extirpated surgically during the first ten or fifteen hours, before actual infection had taken place. In discussing the polyvalent sera-vaccine treatment of wounds Dr. Stewart stated that the polyvalent serum of the French investigators contained the antibodies corresponding to the various inflammations and suppurations, represented by several varieties of staphylococci and streptococci, the colon bacillus, pyocyaneus, and proteus. To these aerobic germs they added several types of anaerobes, the perfringens and septic vibrio. The polyvalent serum was obtained from horses which had been immunized against the different pyogenic organisms. It was originally intended for purely local use as a direct application to infected wounds, but it had also been successfully employed in hypodermic and intravenous injections in certain cases of staphylococcus and streptococcus septicemia. A

method of wound treatment by the introduction of living cultures of a spore bearing anaerobe of the proteolytic group had recently been investigated by Donaldson and Joyce. They made the observation that cases which emitted a bad odor made no headway and that in these cases a certain bacillus was found to be apparently constant, and it was constantly absent from those cases that did not smell. This bacillus acted, apparently in virtue of its proteolytic powers, only on devitalized tissue and possibly on toxalbumins, and appeared to have no power of attacking healthy structures. It succeeded also in attacking microscopically damaged structures. As a result, the body forces were freed from the constant menace of septic poisoning, thus allowing them to begin the work of repair. It was too early to comment on this new departure beyond pointing out that it was an added argument in favor of the growing conviction that the presence of devitalized tissue in a wound represented the real danger element. The fear of opening the chest had now been changed, and a lung, wounded and bleeding, or containing a foreign body, was attacked by making an opening, palpating the foreign body, removing it, and controling the bleeding by suturing, then suturing the chest and expanding the lung. Penetrating wounds of the chest had a mortality which could be estimated at 20 per cent., according to the statements of the Interallied Surgical Conference in 1917. The immediate mortality was highest, due to hemorrhage and asphyxiation. Shock played a prominent part in the immediate and early deaths. The ultimate mortality was usually due to pleuropulmonary infection.

The Inorganic Nervous System and Organotherapy. Dr. JOHN ROGERS of New York presented this paper, in which he demonstrated that there was experimental evidence to prove that definite and prompt reactions could be obtained by the injection into dogs of certain materials derived from the thyroid and other endocrine glands. These reactions showed an intensification of either the activating or the inhibiting function of the different portions of the involuntary nervous system and seemed to be produced through the direct stimulation by the organ extracts of the terminal filaments of these nerves. The stomach was an organ in which the function of its vagus and sympathetic nerve supply had been quite clearly demonstrated and could be well arranged for study by means of a Pavlov or Janeway fistula. Experiments showed that the injection into an animal of the non-coagulable or "residue" portion of a saline extract of the thyroid increased a little more than in the normal dog the quantity and acidity of the gastric juice and atropine inhibited the flow. Adrenalin, after the destruction of the sympathetic, was inert. Tests made with nicotine seemed to show that this drug inhibited the gastric secretion through a paralyzing effect upon the vagus, but less actively than atropine. Residues of saline extracts of other organs were then tested, and it was found that only the entire pituitary acted like the entire adrenalin and apparently through stimulation of the inhibitory power exerted by the sympathetic. The thyroid, the parathyroid, the pancreas, and the spleen, all in different degrees, when the dose was standardized by its nitrogen content, seemed to intensify the activating power of the vagus. Tests of the effects of the thyroid on other organs, though not as complete as those upon the stomach, showed that only the "residue" of a saline extract of thyroid stimulated the flow of pancreatic secretion, apparently, as in the stomach, through the terminal filaments of its vagus nerve supply. It also increased the vigor of the contraction of both voluntary and involuntary muscle fibers, apparently through their nerve supply, and in kymograph tracings it was a vasodilator, but did not cause any appreciable increase in the pulse rate. Tests were then made with alcoholic and ethereal extracts of thyroid, and these were found to be fully as active, if not more so, as the residue of the saline extract. If, however, the extracts were made from thyroid material which had been dessicated, like the commercial thyroid powder, the results showed that their activity was more or less impaired. After freezing, however, the organs could apparently be stored for a long time and the extracts would still be indistinguishable in their effects from those of the "fresh" organs. There was some substance which could be extracted from the thyroid with ether or alcohol, or with a slightly alkaline saline solution, but not with distilled water, which was capable of producing an immediate response in the dog's stomach and other organs. This non-coagulable material appeared to act through the terminal filaments of the vagus and not through the sympathetic, because its effects were prevented or inhibited by atropine and by section and degeneration of the vagus. Furthermore, when administered intravenously and the results noted in kymographic tracings, there occurred vasodilatation and no appreciable increase in the pulse rate. These reactions indicated that the only material capable of producing immediate physiological reactions which could be obtained from thyroid stimulated, not the sympathetic, as generally believed, but the vagus. In the stomach, at least, extracts of pituitary and adrenalin glands, and these extracts contained something more than adrenalin, seemed in different degrees to intensify the function of the sympathetic, while the thyroid, parathyroid, pancreas, and possibly other organs similarly in different degrees seemed to intensify the action of the vagus. If these observations could be confirmed and extended, then there was opened a new chapter in nutrition. When myxedema could be relieved or cured by thyroid feeding, the patient must first of all possess a certain minimum amount of thyroid epithelium which was capable of performing a certain minimum amount of normal biochemistry. If these cells were insufficient in number or had been damaged beyond some (unknown) point, then, both experimentally and clinically, thyroid feeding, although some temporary alleviation of symptoms might occur, was in the end ineffective. This meant that the ingested material, after its passage through the gastrointestinal tract and liver, must emerge into the circulation, probably as an iodized amino acid which could not perform the normal functions of the gland, but must first be absorbed by it as a nutriment and then be metabolized as thyroid product. Dr. Rogers made a practical application of these principles to various clinical conditions and more particularly to that large group of disorders in which the most constant and most important causative factor seemed to be fatigue.

Acidosis in Infants.—Dr. JULIUS LEVY of Newark presented this communication. He said the symptoms of acidosis were hyperpnea, great restlessness, often going on to stupor, marked irregular temperature, ashen gray color of the skin without cyanosis, and great reduction in the urinary output. For several years the essayist stated that he had been following a group of cases which presented some symptoms in common with this syndrome, but were sufficiently distinctive in several particulars to require separate consideration and classification. The clinical picture was that of a child between one and two years of age, usually well kept and carefully fed, who suddenly vomited several times the same day; the temperature was normal, or but slightly elevated, the child very pale, very quiet, apathetic, and rather somnolent. There was no diarrhea and, in fact, the child had been rather constipated and we often learned that the stool was cream colored and greasy. There was often a sudden diminution in the amount of urine. From the severe vomiting that occurred at intervals and seemed to bear no relation to feeding severe prostration set in and these cases had in several instances been mistaken for meningitis and again for appendicitis. After two or three days the vomiting ceased, the child brightened up, had two or three large watery stools, passed more urine, and appeared to be in its normal condition. In a few cases the vomiting occurred several times a day with slight remissions for weeks or months and the child might die from atrophy or acidosis. The urine showed large amounts of acetone and diacetic acid at the onset of the vomiting attack. This point was emphasized to make clear that it was not the result of starvation. On the second or third day small amounts of albumin and a few hyaline casts would frequently be found in addition to the acetone and diacetic acid and in severe cases granular casts and a few blood cells had been noticed. There was found to be a constant correlation between the urinary findings and the vomiting and somnolence, which suggested that this group of cases was one of true aci-

dosis. It was important to recognize these cases so that they were not mistaken for nephritis, appendicitis, or meningitis, and so that the dietetic errors might be corrected. In the treatment of these cases the best results had been obtained by giving daily high irrigation of one pint of water with one dram of bicarbonate of soda, and in addition supplying one dram of bicarbonate of soda mixed with the food, which had consisted of skimmed milk, malt soup, and cereals, with a gradual return to a rational diet. The child's diet usually needed reconstruction with special attention to the caloric requirements and the fat tolerance.

Dr. THEODORE TIEMER of Newark said that while morphological and mechanical conceptions of physiological and pathological processes had dominated medical thought for a long period of time, the application of chemistry to the same problems had within our own time yielded remarkable results. It had not only thrown light on many difficult problems, but it promised to change some of the fundamental ideas in medical science. Depending largely upon the viewpoint of the investigator, various conditions had been described as acidosis, so that the meaning of the term in medical literature had become somewhat hazy. As suggested by Martin Fisher, the term should be used in the original sense as "intoxication with acid." The mere presence of abnormal acid did not mean acid intoxication, but an altered chemistry from which an intoxication might result. Alteration of the chemistry of acid formation and acid elimination might evidently result from metabolic disturbances associated with an interference with the normal production of carbon dioxide. Such was the condition in patients with heart disease with failing compensation, in which an inadequate supply of oxygen was furnished to the tissues. In these cases an increased amount of acid was not only proved by the direct finding of more acid in the blood, but also by analysis of the urine. The same sort of intoxication existed in cases in which the tissue cells, with the maintenance of normal circulation and plenty of oxygen reaching the tissues, were damaged by a poison of some sort, so that they could not use the oxygen after it had reached them. Such cases were represented by the acid intoxication subsequent upon narcosis by ether, chloroform, morphine, and other protoplasmic poisons. The toxemias also seemed to belong to this group. Another form of intoxication was intimately associated with the infectious processes occurring in the body and assuming degrees depending largely upon the intensity of the infection, the nature of the microorganisms, and the duration of the disease process. While the localization of the disease process frequently dominated the whole clinical picture, the acid intoxication usually exerted a generalized effect and its importance was frequently underestimated. Dr. Tiemer then discussed another group of acid intoxications dependent upon disturbances of metabolism in the narrower sense—disturbances in which the utilization of food materials necessary for maintenance of health had become defective through more or less profound changes in the agencies governing these metabolic processes. The classical example of such metabolic disturbances was furnished by diabetes mellitus. This form of relative acidosis described by Dr. Levy was of special interest to the pediatrician, as it frequently occurred in infants that had been overfed with fats. The feces of such infants contained more alkali than had been supplied in the food and which must, therefore, have been derived from the fixed bases of the body. If fat overfeeding were continued for a long time a peculiar symptom complex might become established which depended upon the withdrawal of alkali. The possibility, however, existed that some of the symptoms presented by such infants were dependent upon a superimposed true acid intoxication due to disturbed metabolism. Other children, ranging from two to eight years, actually showed clinical symptom complexes which had been interpreted as due to a true acidosis, like the cyclic vomiting. It must be admitted, however, that good observers considered cyclic vomiting as a form of hysteria in children and the appearance of acetonuria in such cases as only secondary to the profound disturbance of nutrition.

Dr. HYMAN I. GOLDSTEIN of Camden said a lot of material had been presented by these gentlemen, but, as he understood it, the subject was, first, acidosis, and, second, acidosis in infancy, and not acetonuria. He disagreed with the writer of the paper when he said that we did not know more about acidosis than we did about eclampsia. We knew the chemical cause of acidosis and certainly we knew that recurrent vomiting was not hysterical, because in recurrent vomiting the chemical examination showed urates and acid phosphates increased in the blood, and this was not shown in hysteria. One never heard of bicarbonate being given in hysteria, but we obtained good results from its administration in recurrent vomiting. Dr. Levy gave the impression that he made the diagnosis of true acidosis on the basis of acetone in the urine. That had prompted him to speak, for he wished to emphasize the insignificance of acetonuria in acidosis. Those cases might not have been true acidosis, but may have been due to infections or something else. There might also have been acetonuria in addition to a true acidosis. In true acidosis there was a diminution of acetone in the urine. About 50 per cent. of children suffering from various conditions had acetone in the urine, but one never treated a case as a true acidosis simply because of the presence of acetonuria.

Dr. ALEXANDER MARCY of Riverside emphasized the fact that all cases of acidosis were not necessarily cases of cyclic vomiting, but in addition to the cyclic vomiting one might have acidosis. Some one had said that cyclic vomiting was hysterical. He was willing to admit that there was a large nervous element and that there was something periodically wrong with the nervous system in cyclic vomiting. The physiological mechanism was disturbed and there was acidosis, but there was certainly something more than acidosis. Anyone who has seen a severe case of cyclic vomiting has seen one of the most awful things a child could go through. These children before they had acetonuria had indican in the urine, and after the indican had appeared the acetonuria followed. Undoubtedly treatment in these cases was useless; the attack ran its course and after a given length of time the child recovered. He had seen one case that proved fatal, in which an autopsy was made and it was found that the liver had undergone fatty degeneration and the kidneys showed an acute parenchymatous nephritis. Every organ of the body had undergone acute degenerative changes and yet that child had been apparently a perfectly healthy child. This case had occurred years ago. Now, in such cases they began immediately saturating the patient with bicarbonate by way of the mouth and through the rectum and they took away food. He always approached a case of cyclic vomiting with fear lest it be accompanied by degeneration such as he found in this case.

Dr. F. H. TODD of Paterson said that sometimes in focusing their attention on the symptoms of acidosis they said too little about the cause of this condition. Personally they all agreed that acidosis was of intestinal origin and had its foundation in high fat and high protein feeding. Under such conditions changes must take place in the intestinal tract, changes in the bacteria which gave rise to a mass of purins which broke up the fatty acids and these were absorbed and the only symptom was acidosis. Nephritis was a natural consequence and pathological changes in the liver were perfectly natural. The vomiting was not due to any changes in the stomach itself, but to the absorption of toxins from the intestinal tract. Acidosis was the same thing as cyclic vomiting and the reason it came on periodically was because there was a gradual accumulation of the products of the fatty acids and when they had reached a certain amount there was a sudden attack of acidosis with vomiting. The treatment indicated was to neutralize the acid and inhibit the growth of intestinal bacteria. The point to be emphasized was that acidosis was only a symptom of the real trouble.

Dr. DAVID E. ENGLISH of Summit expressed the opinion that we could not make acidosis a disease by itself. It occurred in the course of so many diseases that to make it a separate entity with a specific cause was a mistake. He wished to call attention to the connection between cyclic vomiting in infancy and migraine in the adult. He had lived long enough to see babies

that had suffered from cyclic vomiting grow up and have migraine, and he believed the cause of both conditions was the same, namely, a lack of development or an overdevelopment of some endocrine gland. He did not know which one, and perhaps it was not always the same one. He believed in the bicarbonate treatment, whether the condition was due to acidosis or not, because it had a good effect. That had led him to think that bicarbonate of soda might have a beneficial effect in migraine, and he had tried it with considerable success.

Dr. Levy, in closing, said that what he had wished to bring out was that there was a clinical entity, somewhat different from the laboratory idea; scientifically it might not exist, but clinically there was such a thing. There was such a thing as cyclic vomiting, but that was not what he was speaking of. He meant a type of case not as frequent as the gastrointestinal case. These patients were helped by cleaning out and by bicarbonate, but they should not be starved. A second point he wanted to bring out was that they should get rid of the idea that bacteria were the cause of all digestive disturbances. The type of case he was describing was due to a metabolic cause, and was likely to be due to high fat and high protein feeding. There was also a type of case that ran for weeks or months, which was that to which Dr. Marcy probably referred. Not every case that had aceton in the urine was a case of acidosis, but a case of acidosis might have aceton in the urine together with the other symptoms that he had mentioned, and these cases should be treated as he has described.

Hospitals and Hospital Standardization.—Dr. John M. Baldy of Philadelphia made this address, in which he stated that the general trend of hospital development was good. The surgeon had been the pioneer in hospital work, because for the development of surgery hospital facilities were essential. To-day the internist was in the same position as the surgeon was fifteen or twenty years ago. It was impossible without the laboratory to develop a good internist. Every community having a hospital should also have a laboratory in connection with that hospital or cooperating with it. The day had long gone by when the hospital could be looked upon as simply a place in which to care for the sick. That was the prime function of a hospital, but there were others that went with it. The hospital should be an instrumentality for the education of the coming medical man, of the staff men, of other doctors, and of the people of the community as to what the proper practice of medicine was. Without the educational feature as a safeguard it was absolutely certain that the patient was not well cared for. The community had cmoe to understand that better treatment could be obtained in a hospital than elsewhere and they were demanding this treatment. Any person who sent a servant to an institution and who saw the laboratory examinations that were made and the intensive study given the case was not going to have himself treated by prescription writing. Every man when he started out to practise medicine should have the facilities to practise medicine as he had been taught to do. Complaints were heard that men could not be found for the laboratories in the smaller towns. He had been advising those who made that complaint to take the last young doctor who had come to the town and put him into their institution. These young men were proud of being connected with the institution, and they knew how to work and would develop the institution. They also served to arouse competition and to set a new pace for the older men.

Oration in Medicine—War Strain and Shell Shock.—Dr. M. Allen Starr delivered this oration, in which he stated that the terms "shell shock," "war shock" and "war neuroses" had been coined and had proved very convenient, as they did not commit one to any particular pathology or diagnosis. He discussed the etiology, pathology, and symptoms of the condition, calling attention to the points whereby shell shock might be differentiated from injuries of the brain or cord. He said it was admitted by all investigators that the chief etiological factor in shell shock was the long continued emotional strain. But this produced many pathological effects and could not be dismissed with the label of mere hysteria. Back of the lines before the men got into actual trench service they heard tales of the strain which others had undergone, of the shocks they had suffered, and they saw the wounded and the nervous and mental wrecks coming back from the front. When the man finally got into the trenches he was subjected for a period of three to seven days to a continuous nervous strain, living in ceaseless noise, in constant danger, with little or no sleep, and in a constant state of excitement and apprehension. Both private and officer were subjected to mental strain to which they were wholly unaccustomed. In this connection Dr. Starr referred to the effect of emotion on bodily activities, reviewing the investigations of Cannon of Harvard, Crile of Cleveland, and Heckel of Paris. As Crile pointed out, anger and fear directly affected the adrenals and the thyroid secretion and he likened the condition present in fear to that in exophthalmic goitre, with staring eyes, marked pallor, and the profuse sweat, diarrhea, and general tremor, which he produced in his animals under a state of alarm. The mental state which had been described as characteristic of the soldier in the trenches was far greater in its intensity of emotional content than that which could be produced in laboratory animals. There were many proofs that each of the pathological effects described by the physiologists as occurring in animals were present in cases of war neurosis and, therefore, in the study of the symptoms it was manifest that no mere dismissal of them lightly with the designation of hysteria in any way met the case. In the study of the symptoms of shell shock we must recognize not merely the mental attitude, not merely the emotional element, but also the physical effects which this attitude and emotion inevitably produced, unconsciously to the sufferer, but none the less manifest to the physician, and we could not expect relief from these symptoms until there was a spontaneous subsidence of the physical and chemical conditions which this emotion had produced. The symptoms which appeared under the conditions of war strain were so numerous and differed so greatly in different cases that it seemed necessary to classify them by distinguishing between the mental and the physical symptoms. The physical symptoms might be divided into motor, sensory, reflex, and sympathetic. The motor symptoms were in many cases most striking from the beginning and included tremor, sometimes active spasmodic contractions, torticollis, shrugging of the shoulders, playlike movements of the arms, kicking movements of the legs, all of which interfered with voluntary movements and resembled regular types of chorea. All these motor symptoms appeared to cease during sleep and many of them could be arrested by hypnosis. Paralysis might appear as a motor symptom, though its characteristics were not those occurring in organic disease, as there was no muscular atrophy, no change in the reflexes, and no loss of electrical response Marked contractures of a bizarre type of the hands and feet were frequently seen. The gait was peculiar, the feet being dragged along as if weighted, and staggering and falling were common. Among the sensory symptoms the special senses were very often affected, blindness, deafness, hemianesthesia, and mutism being not uncommon. Sudden restoration of sight and also of hearing under hypnosis had convinced all observers that the loss of sense was functional. The blindness was never attended by atrophy of the optic nerve or a change in the optic discs and the deafness was not attended by vertigo. The reflex symptoms consisted of hyperexcitability of the skin to irritation, resulting in initial pallor, followed by flushing and urticarial-like swelling of the surface, but a loss of skin reflexes had not been observed. The deep reflexes might be slightly exaggerated, but ankle clonus and a Babinski reflex were absent. The sympathetic or vegetative symptoms were marked in very many instances. A rapid, irregular action of the heart, irregular respiration, defective digestion, glycosuria, and polyuria, irritability of the bladder and rectum without loss of control, and symptoms pointing to an irregular and imperfect action of the ductless glands were very common. Both hyper and hypo-thyroidism had been observed. A curious form of aphasia was quite common, in which the patient appeared to be quite unable to utter a word, though able to understand and to write his thoughts and wishes. In organic motor aphasia writing was

impossible. There were further evidences that in shell shock there were actual pathological conditions not at all psychical. Mott had recorded a number of cases in which minute capillary hemorrhages had been found in the brain, scattered through both gray and white matter, and hence capable of arresting the action not only of the brain cells which received, stored up, and sent out impulses, but also of the connecting fibers which associated these impulses, and subserved of the memory, reasoning and self-control. Recovery did not necessarily militate against this pathology. Another pathological condition to be considered was multiple thrombi through the brain from gas bubbles. It was known that when, as in caisson disease, an artificial atmospheric pressure was suddenly removed from the body such bubbles formed in the blood, just as when bubbles appeared in champagne when the bottle was uncorked. By observation with aneroid barometers it had been shown that when a large shell exploded it produced an air pressure of ten tons to the square yard on all bodies within fifty feet. This sudden pressure was followed by a sudden relief of pressure, hence the secondary effect of the explosion was comparable to coming out of a caisson. Thus multiple gas emboli might occur in men in the trenches and throw the soldier into a state like that seen in caisson disease. Here again recovery was not impossible. The *mental* symptoms were particularly common and, though some of the cases were diagnosed as insanity, they did not correspond to the typical forms of insanity. Among the symptoms particularly frequent were disturbance of the consciousness and personality, disturbance of memory, and an emotional condition characterized by great depression and distress of mind. The patients were often content to sit and brood and cry. They had no definite delusions of a melancholic character. It was a primary emotional state rather than a reasoning depression. Relapses into this condition from time to time during the process of recovery were frequent. Impairment of the will power was another symptom which occurred. The power of self-direction, of control of the flow of thought, of the control of emotions, and even the power of control of voluntary activity was lost. Morbid impulses and morbid ideas were very frequently manifested, leading to the most unusual and irrational acts. Fits of terror were very common in both the mental and the physical cases. This was not a manifestation of cowardice, for a coward preserved his instinct of self-preservation and tried to escape or to protect himself and did not recover his equanimity until he was safe. In shell shock terror there was a complete mental paralysis, with no attempt at safety. As to the treatment, in some complete rest, relief from anxiety, the assurance that return to fighting was impossible, happy surroundings, diversion, productive occupation, and good nutrition were the chief remedies. In others a process of encouragement to stimulate the will was needed. Re-education was the means of restoring to health many of the victims of shell shock. To-day in England and Canada hundreds of devoted patriotic women were laboring in hospitals with these men, teaching, encouraging, stimulating them to resume normal activity. Preparation for this work was being made in New York City by several agencies. It was not wise to send these patients home to anxious relatives, where a recounting or exaggeration of symptoms only excited interest and there was little stimulation to recovery. Shell shock must be treated by those who were especially interested and fitted by previous training to handle the mental and physical conditions which were so multiform and so perplexing. In every case the will to recover, like the will to win, was half the battle.

Address of the Third Vice-President—Is It Good Practice for the Surgeon to Perform Visceral Exsections and Resections While the Viscera Are Inflamed?—Dr. PHILANDER HARRIS of Paterson read this paper. He recalled that many years ago he had registered a protest against immediate operation in every case of acute appendicitis. On July 2, 1903, he saw, with a very dear medical friend, a case of appendicitis upon which it was desired that he should operate at once. It was then but a few hours after the onset of the first symptoms and it was the patient's first attack. He advised against operation, but at the insistence of others operated, and the young man died within eighteen hours. Since that time he had not operated on any case of appendicitis in the attack, except for the purpose of the evacuation of appendical abscess and establishing drainage. He had seen many cases and carried the patient through the attack without death, and from very many of them he later removed the appendix at a time when the patient was in a condition more safe for operation. After this prelude the writer discussed the subject of viceral inflammation in the abstract. Inflammation was always a secondary condition and must be regarded as a reconstructive process, and was only incidentally or unwillingly a destructive one. The pain produced by inflammation was a wise provision of nature, and suggested, invited, or compelled the individual of his own initiative to rest. The early arrest of peristalsis was the most potent factor in effectually walling off an injury to the pelvic or abdominal viscera, and an early and complete walling off was the very particular condition tending to limit the field of infection, and thus sequester the injury or infection and lessen the draft of the vitality of the individual in his effort to recover. As experience had proved that almost all cases of infection of the gallbladder, appendix, and Fallopian tubes might be carried through an acute attack without fatal issue, should we interfere with nature by going counter to her tendencies? The intrusion upon nature by untimely operation might make recovery impossible, and in cases thus prematurely operated on which did finally recover a new and large area of tissue had been exposed to infection and healing was thereby delayed.

Patriotic Addresses.—Lieutenant-Colonel F. F. SIMPSON of Pittsburgh said that as a nation we were irrevocably committed to such a course of action as would secure an enduring peace with liberty. That meant that every man, woman, and child has committed himself or herself to perform the maximum service of which he or she was capable. In considering the duty of the medical profession it was sometimes necessary to take a broad view of the subject. In reviewing the task that lay before America the first fact that stood out was that America had a divided enemy. Germany was fighting from two centers; she had an invisible army in America and a visible army in Europe. The Germans, whose chief mental characteristic was to make a map of everything and to calculate everything to the most minute point, had taken a close account of the vast stretch of territory in this country, of the enormous population, of the immense stores of raw material and food; all these she had planned to grasp and stood ready to stamp with her iron heel. She intended to do here what she had done in Russia and Belgium and Roumania. The only thing to do here was to have a better and a quicker preparation and to strike first and fast. It was estimated that for every 1,000,000 men in times of peace 7,000 medical men were required; for the same number in times of war 10,000 doctors were required. By August 1 of this year it was calculated that there would be 3,000,000 men under arms; that would mean that 35,000 medical men would be needed. It would be seen by this that the doctors must respond from every county and from every State in the Union. He had no doubt that the medical profession would respond to every demand made upon it and that they would respond voluntarily. That would take many vigorous men from the communities, institutions, and industries of the country. This was going to create a problem which we should go about solving in a sane and sensible way. The institutions and industries must be classified, and we must adjust our supply of doctors to their needs and do the best we could with the man power allowed to remain at home. We might rest assured that the Surgeon General would make the best possible use of the man power that went to the front. In the war hospitals the care given the soldiers would be of the best. The internes in these hospitals were taken from the chiefs of staffs of the civil hospitals, while in the large civil hospitals the internes were the recent graduates. The young men were willing and anxious to serve the nation, and were offering to assist in this problem of the readjustment of the civilian medical fabric of the nation to meet the war needs. The medical profession, in addition to its services to the nation and to the civil population, had

another duty. That was in reference to the invisible enemy in this country. We had among us many spies who had an insidious way of appealing to the best sentiments of men and through them undermining the unity of our nation. They had tried this plan of crushing the pride and undermining the morale of the people of Italy and for the moment the Italian people were taken off their feet, but the patriotism and loyalty of the Italian people were soon crystallized with such firmness that they would never again be the dupes of deceptive German agencies. The same thing was going on in this country. Whenever we saw references to pacifist propositions we might put it down with mathematical precision that they were made in Germany. The medical profession could exert a powerful influence in combating this invisible army.

Dr. Joseph MacDonald, Jr., spoke briefly of the needs of the Government for medical men. He said many physicians said that when they were needed they would go, but there never was a time when they were needed more than at the present moment. There were in the State of New Jersey 2,935 male practising physicians, 679 of whom were in the Medical Reserve Corps and 650 were over age. From these figures it might be seen that there was still ample material to furnish not only one quota that the Government has asked from New Jersey, but many more.

Dr. Harold D. Corbusier of Plainfield made an address in which he pointed out that there were two ways in which the medical profession could serve. One was by staying at home and picking up various activities that were helpful in winning the war and by influencing the younger men in the profession to go into the service, and the other way was by actually getting in oneself. Figures had been given which showed the number of men that were needed, but it must be remembered that we would have to keep on supplying men, whether infantry or artillery, or whatever the branch of the service. Some men would be killed and some would be retired, and we should have to be constantly filling up the ranks. Many men thought they could not go into the service and they gave very excellent reasons, but if they would get to thinking the matter over and trying to adjust their affairs they usually found a way. There was a place in the service for specialists as well as for general practitioners of medicine. The speaker urged men when they enlisted to say they were internists if that were the case. Nearly every man who enlisted said he was a surgeon. Internists were needed, and laboratory technicians and *x*-ray men were needed. The speaker described the routine duties in camp and the training camp activities, and emphasized the importance of this training for the medical men who wished to serve in the Army.

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-Third Annual Meeting, Held at Philadelphia, May 16, 17 *and* 18, 1918.

The President, Dr. John G. Clark of Philadelphia, in the Chair.

President's Address: Medical Teaching and Research After the War.—Dr. John G. Clark of Philadelphia selected this topic for his address and presented the following conclusions concerning the scholastic maintenance of gynecology and obstetrics: (1) An adequate endowment or an annual budget of not less than from $25,000 to $30,000 a year for salaries would render it feasible to combine the departments of obstetrics and gynecology. Some of the advantages of this plan were stated as follows: (*a*) There would be less duplication of teaching in embryology and in the anatomy and physiology of the female reproductive organs. (*b*) The pathological aspects of the two subjects could be correlated, making only one laboratory necessary. (*c*) As many of the diseases were referable to the child bearing process, they might well be grouped under one head. (*d*) The opportunity was afforded of studying in the obstetrical department the results of various operations and the remedial measures employed for the relief of gynecological diseases. (2) When an endowment was not sufficiently large to equip fully and maintain a combined department in the most comprehensive way, or when special endowments for the maintenance of an obstetrical and gynecological department could be secured, but were not large enough to allow the chief assistants and director to retire from private practice, such departments might be conducted more successfully as separate units, for the following reasons: (*a*) In a university medical school special departments were likely to turn out a more refined product and to offer better instruction if the field to be covered was not too extensive. (*b*) When properly endowed, the department of gynecology might very logically expand and enter the domain of general surgery. The chief function of the head of such a department was that of instructor in diseases of women, and in a minor role of clinical teacher of abdominal surgery. (*c*) With separate chairs, more time could be given in the obstetrical department to the teaching of the very important subject of diseases of nursing infants, a subject that was now receiving inadequate attention for the reason that the obstetrician had no time to devote to this branch.

Fetal Anatomy of the Female Pelvis.—Dr. Fred L. Adair of Minneapolis based his report on two studies: (*a*) the ossification centers of the fetal pelvis, and (*b*) a wax reconstruction of the pelvis of a female fetus of 14 weeks gestation. The first part of the work was based on observations of 14 *x*-ray plates of fetuses, 21 transparent embryos and 25 sets of serial sections. From these two investigations the following conclusions were drawn: "(1) The first ossification center of the pelvis appears in the ilium about the 60th to 65th day of fetal growth in embryos with a C. R. length of from 30 mm. to 35 mm. (2) The median center of the first sacral vertebra is the next to appear about the 74th to 76th day in embryos having a C. R. length of 51 or 52 mm. (3) The lateral sacral centers appear when two or three median centers are present, in embryos 80-82 days old having a C. R. length of 65 mm. (4) The ischial center appears about the 94th to 98th day in embryos whose C. R. measurement is from 88 mm. to 100 mm. (5) The pubic center is present on the 129th day in an embryo with a C. R. length of 150 mm. At this time all other centers which appear, until just prior or subsequent to birth, are usually apparent. (6) Practically all antenatal pelvic ossification centers are evident by the end of the 19th week of fetal life. (7) The skeletal pelvis resembles closely that of the adult in its form and markings. Most of the structures of the adult are indicated in the fetal pelvis. (8) The most striking differences between the adult and fetal pelvic skeleton are: (*a*) The second sacral vertebra occupies, in early fetal life, about the position of the last lumbar in adult life. (*b*) The short distance between the ischii which lie almost parallel in the fetus. (*c*) The very acute pubic angle (15°). (9) The absence of sacral concavities in the fetus. (10) Sex differentiation is well marked in this specimen on the vulva, most of the different structures in the external genitalia being easily recognizable. (11) The vagina is well formed. The cervix is relatively large; the corpus occupies about its adult relations. flexures, and position. It is flattened anteroposteriorly. (12) The two tubes show marked differences in length, source and height as well as in their relations to the ovaries. (13) The ovaries are large, being much bigger than the uterus. The two differ in their relative positions. They both lie above the pelvic brim. (14) The bladder is well differentiated from the rest of the urinary tract. It is distinctly an abdominal organ. (15) The ureters and arteries stimulate the adult relations. (16) The development of the rectum and anal region is well advanced and corresponds approximately to the adult type. The colon enters the pelvis in the mid line and appears not to have been filled with meconium."

Escape of Foreign Material from the Uterine Cavity into the Uterine Veins.—Dr. John A. Sampson of Albany, N. Y., stated that radiographs of the uterus, tubes and ovaries in which the uterine cavity had been injected with bismuth (introduced through the cervix) showed the form of this cavity under various conditions: and also by what channels and under what circumstances the bismuth might escape from the uterus. If the tubes were patent the bismuth escaped into them;

the ease with which this occurred varied with the degree of patency of the tubes. These experiments suggested that intrauterine irrigations were attended with the danger of some of the irrigating fluid, at times, escaping through the tubes into the peritoneal cavity; and also that fluid in the uterine cavity, under favorable circumstances (patent tubes, relaxation of uterus and obstruction in the cervix) might be forced into the tubes and peritoneal cavity. This was one way that salpingitis and peritonitis might arise. If the endometrium was intact the bismuth would not escape into the venous uterine sinuses even though great force was used. If the patient was flowing when the uterus was removed the bismuth might gain access to them. If the endometrium was removed by curettage, the injection mass would usually escape into these sinuses. The ease with which this occurred varied with the size of the sinuses in the individual specimen and the degree of relaxation of the uterine wall. Under favorable circumstances of venous hyperemia and uterine relaxation, the bismuth easily escaped into the venous sinuses and into the venous circulation outside of the uterus. A study of uteri in which the venous system had been injected with bismuth through the uterine and ovarian veins showed a rich venous plexus in the endometrium and also one in the myometrium; the latter might be subdivided into a peripheral and radial plexus, situated in the peripheral and radial zones. Arcuate veins between the two zones conveyed the venous blood to the uterine plexus between the layers of the broad ligament. Relatively large sinuses (receiving) radiated from the base of the endometrium into the myometrium and conveyed the blood from the endometrial plexus into the deeper portion of the radial. If these receiving sinuses were exposed by removing the overlying endometrium and the uterus was relaxed, thus holding the lumina of the receiving sinuses open, fluid and small solid material could easily escape from the uterine cavity into them and thence into the venous circulation outside the uterus. Clinical experience had taught us that solid material from the uterine cavity gained access to the venous circulation—puerperal infection and the presence of placental cells (benign and malignant) in the lungs of puerperal women. Experimentally solid material (bismuth in suspension) could be forced from the uterine cavity into the venous circulation under very little pressure if these sinuses were exposed and the uterus relaxed. Anatomical and physiological studies demonstrated how this might occur, exposure of the lumina of the receiving sinuses, uterine relaxation, and pressure in the uterine cavity greater than that in the sinuses. He believed that uterine contraction following relaxation, when there was obstruction in the cervical canal and intrauterine irrigation might bring about this increased pressure and force fluid, sterile or containing in suspension bacteria or placental cells, into the venous circulation, one way, and probably a frequent one, by which puerperal infection arose and placental cells reached the lungs.

Dr. George W. Kosmak of New York City said that the work of Dr. Sampson was a striking demonstration of the warning that we ought to stay out of the uterus as much as possible because the invasion of this organ, particularly in the puerperal state and at other times, was attended with a great deal of danger. Observations which he made some years ago with reference to the extrusion of irrigating fluid through the Fallopian tubes demonstrated this to him in such a dramatic manner that he should never forget the subject, and Dr. Sampson's remarks not only clearly demonstrated but had shown most convincingly the possibility of the invasion of the general venous system by mechanical methods, as he had demonstrated by his injection specimens.

Dr. John O. Polak of Brooklyn, N. Y., said the demonstration of the protection of the endometrium against invasion from curetting the uterus was particularly impressive. Years ago we were taught not to operate during the menstrual period, yet in the hurry of hospital work we had violated the rule. Dr. Sampson had given us a clear idea of why in some cases we got infection.

Dr. Thomas J. Watkins of Chicago thought the paper was of great value in bringing before us positive evidence against curettage of the puerperal uterus, and the society should put itself on record against any such procedure. Whenever the question of puerperal infection came up before a body of gynecologists and obstetricians, it was to him surprising and shocking the number of men who continued to curette and wash out the puerperal uterus. Dr. Sampson had presented an excellent argument against it. He related briefly a series of investigations which he had made bearing on the subject. The uteri in 200 cases, which were removed by hysterectomy, were examined bacteriologically by Dr. Curtis, and an interesting point was this: In nearly all these cases the endometrium was sterile, whether it was a chronic case or not, except in those in whom a preliminary curettage had been made. If the curettage had been done two or three days or two weeks before the hysterectomy, and done under aseptic precautions, invariably the uterus was found to contain bacteria following such a curettage; and the work of Dr. Sampson emphasized the danger of increasing infection by curettage, and especially increasing the dangers of doing hysterectomy a few days after the preliminary curettage.

Dr. J. Wesley Bovee of Washington, D. C., said that the work of Dr. Sampson confirmed what he had been doing in the last few years, namely, discarding frequent curettage that was so common—and he feared too common now—and he, still clinging to the necessity of having to invade the uterine cavity, injected iodine into it. In two specimens in which he had injected iodine previous to removing the body of the uterus within ten days for Neisserian infection, he found iodine in the blood channels in the uterine body, so that caused him to discard injections of iodine. Then came the paper of Dr. Curtis, which showed the interior of the uterus was nearly always a harmless structure above the internal os, and now came Dr. Sampson's paper, which confirmed that position.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Colorado Board of Medical Examiners.

Denver, April 2, 1918.

(*Concluded from page* 574.)

OBSTETRICS.

1. Describe local maternal changes at end of first half of pregnancy.
2. Give your method of conduct of a normal labor.
3. Describe the mechanism of labor of an L. O. A.
4. Name the positive signs of pregnancy.
5. Etiology, symptoms, diagnosis, and treatment of puerperal insanity.
6. Diagnosis and treatment of placenta prævia at the eighth month.
7. Indications and contraindications for use of forceps.
8. (*a*) How would you control post-partum hemorrhages? (*b*) How deliver the after-coming head?
9. (*a*) Describe the clinical course of extrauterine pregnancy. (*b*) Differential diagnosis of ectopic pregnancy. (*c*) What would you carry in your O. B. bag?
10. (*a*) Describe briefly your conduct of the puerperium. (*b*) Name the three most frequent causes of hyperemesis gravidarum.

SURGERY.

1. Discuss acute osteomyelitis.
2. What are the symptoms and diagnosis of intestinal obstruction?
3. Give symptoms and diagnosis of cerebral abscess.
4. Describe a tuberculous abscess.
5. Give symptoms, diagnosis, and prognosis of fracture of the surgical neck of the humerus.
6. What are the symptoms produced by gallstones?
7. What are the clinical characteristics of a malignant tumor?
8. Give the symptoms and diagnosis of tuberculosis of the shoulder joint.
9. Discuss fractures of the upper third of the femur.
10. Discuss congenital clubfoot.

ANSWERS.

OBSTETRICS.

1. The *local maternal changes at the end of the first half of pregnancy* are: The uterus is enlarged, the cervix is softened, the vagina is softened, congested, and has a violet hue, the vulva is thickened and its secretion is increased, the breasts are enlarged and distended and the secondary areola is observed with enlargement of Montgomery's tubercles, striæ may be seen on the abdomen, menstruation is absent.

2. *The patient* should receive a full bath before labor begins and all bed clothing and personal clothing should be clean. If there are any pathological discharges from the genitals, the vagina should be thoroughly scrubbed with tincture of green soap and hot water, followed by a mercuric chloride douche (1:2000); this followed by a douche of sterile water. The physician's hands should be scrubbed for ten minutes with tincture of green soap and hot water, followed by alcohol, and immersion in mercuric chloride (1:1000). All instruments should be boiled for ten minutes or immersed in mercuric chloride (1:1000) for half an hour. Examinations should be made when necessary to determine the position, presentation, size of the fetus, etc.

During the first stage a rectal enema of soapsuds with turpentine (℥1) should be given, and when the os is dilated to the size of a silver dollar, the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half-hour for three doses.

During the second stage examinations should be made only when necessary. In multiparæ, the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.

During the third stage ℥1 of fluidextract of ergot is administered and irritation of the uterus by friction through the abdominal wall is practised for ten to fifteen minutes. If the placenta is not expelled by this time, the uterus is firmly grasped between the thumb and four fingers and compressed. Firm pressure is then made from above downward and backward in the direction of the pelvic canal. This usually causes delivery of the placenta. A vulvar pad of salicylated cotton and carbolized gauze and an abdominal pad and binder are then applied.—(*Pocket Cyclopedia.*)

3. *Mechanism of Labor in L. O. A.*—"(1) Accommodation of the size of the fetal skull to the size of the pelvic canal by flexion; accommodation of the shape of the fetal skull to the shape of the pelvic inlet by moulding; accommodation of the direction of the head to the direction of the pelvic canal by lateral inclination. These movements occur prior to labor, when the head enters the pelvic inlet with the subsidence of the uterus. (2) Further flexion, moulding, and accommodation of the head to the pelvis by lateral inclination, when labor pains appear, and the head is subjected to a propulsive force and to the resistance of the lower uterine segment, the cervix, and the pelvic walls. (3) Dilatation of the lower uterine cavity and of the cervical canal. (4) Descent of the head to the pelvic floor, mainly by an extension of the fetal spine. The fetal body, as a whole, is not yet propelled along the birth canal, because, during a pain and while the head is obviously descending to the pelvic floor, the fundus uteri and the breech do not sink to a lower level. On the contrary, there is a slight elevation of the fundus, and elongation of the uterus, and the distance between the head and the breech increases during a uterine contraction. (5) Anterior rotation of the occiput. (6) Propulsion and extension of the head in the direction of least resistance under the pubic arch until it is delivered, again following the direction of the lower pelvic floor, which is now upward, forward, and outward. (7) Restitution. The rotary movement of the head is not followed by the shoulders. As the former escapes from the vulva with the sagittal suture running anteroposteriorly, the neck is necessarily twisted. As soon as the head is released from the forces which compel its rotation, it immediately resumes its natural relationship with the shoulders, which lie with their long axis in the oblique diameter of the pelvis. (8) External rotation. This movement of the head is explained by the movement of the shoulders within the birth canal. (9) Descent, rotation, and birth of shoulders. The anterior, or right, shoulder first strikes the resistance of the pelvic floor. In obedience to the universal law that whatever portion of the fetal body first encounters this resistance is directed downward, forward, and inward, the anterior shoulder is compelled to travel in these directions by a rotary movement of the shoulders on the spine. The anterior shoulder finally appears under the arch of the symphysis; unable to move further forward, the posterior shoulder and arm are propelled over the floor of the pelvis and are born, their escape being followed by the birth of the anterior shoulder and arm. (10) Delivery of remainder of the body by a movement so rapid that the eye cannot well follow it, the birth canal being so widely dilated that its walls offer no resistance to the escape of the small and compressible thorax, abdomen, and lower extremities."—(From Hirst's *Obstetrics.*)

4. *Positive signs of pregnancy.*—(1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation, and (5) the umbilical or funic souffle.

5. *Puerperal insanity.*—Heredity and personal predisposition, exhausting and debilitating conditions, postpartum hemorrhage, excessive lactation, intoxications, primiparity, mental distress, and septic infection are generally given as the etiological factors. The condition generally comes on early, in the first week; it is of a maniacal type, and may be suicidal or infanticidal; persistent insomnia is said to be a precursor of this insanity; when menstruation returns the condition often improves. Puerperal insanity is to be distinguished from lactational insanity; this latter generally comes on later, about the fourth month, and is apt to be of a depressed and melancholic type. The patient must be constantly attended and watched so that she may not hurt herself or her child; sleep and nutrition should be secured; commitment to an asylum or sanitarium may be necessary or advisable.

6. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment, and may be near or over (partially or completely) the internal os. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Treatment:* Stop the hemorrhage by vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

Treatment before term: Rest in bed, with or without a *tampon*, will arrest hemorrhage for the time; the sinuses are closed by thrombi, and the case may go on to term or another hemorrhage. The patient should be allowed cold drinks; opium may be used where pain is present. If the hemorrhage is great, it is safer to induce labor at once than to wait. Occasionally no hemorrhage occurs during pregnancy, not even in labor.

7. *Indications for the use of forceps are:* "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A. Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B. Evidence

of fetal exhaustion (pulse above 160 or below 100 per minute.) 3. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."—(From Jewett's *Practice of Obstetrics.*)

Contraindications: Mechanical obstruction in the parturient canal; incomplete dilatation of the os; nonrupture of membranes; non-engagement of the presenting part; the fetal head being too large or too small; distended bladder or rectum.

8. (*a*) *Treatment of postpartum hemorrhage:* Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

(*b*) *Extraction of the after-coming head:* "If the arms are extended by the side of the child's head, they should be delivered first. The posterior arm is located by the position of the trunk and shoulders. To deliver the right arm, the child's ankles should be grasped with the left hand, and the body raised upward and outward over the mother's right thigh. The fingers of the right hand are passed along the posterior surface of the arm beyond the elbow. The fingers are hooked in the elbow, and traction is exerted; the forearm is then delivered by extension. The left arm is delivered in a similar manner. In the *Wiegand-Martin method* extraction of the after-coming head is effected by the insertion of the index finger of the supinated right hand into the child's mouth and making traction upon it, while pressure is exerted through the abdominal wall by the left hand. In the *Mauriceau* or *Veit-Smellie method*, in addition to the right hand index finger in the mouth, the left hand is also introduced into the vagina, along the back of the child, the middle finger presses against the occiput, while the remaining fingers exert traction over the clavicles. In the *Prague method* the child's ankles are grasped in the right hand, the fingers of the left are flexed over the clavicles, and traction is made. In these methods, when the perineum is distended, the child's body is raised toward the mother's abdomen. *Forceps* may be applied after the child's body has been raised and traction made in the direction of the axis of the parturient canal."—*Pocket Cyclopedia.*)

9. (*a*) Ectopic gestation. *The Symptoms* for the first few weeks are exactly similar to those of normal pregnancy. Later, sharp, cramp-like, periodic pain occurs and is reflected down one thigh. About the third month menstruation returns. The bleeding is profuse and attended by some pain. Flesh-like masses (decidua) are discharged. Nearly all the signs of normal pregnancy are present. Physical examination will reveal a softened cervix, an enlarged and displaced uterus, and the presence of a small cystic tumor, sensitive and adherent, on one side of the uterus. *Rupture* is attended by great pain and syncope. If the hemorrhage is intraperitoneal and extensive, death results in a few hours, attended by symptoms of profound shock; rapid, weak pulse, blanched, cold skin; sighing respiration, and fall of temperature. If the hemorrhage is extraperitoneal, it will be limited and the symptoms of shock and bleeding will be slight. Before rupture the diagnosis is difficult, but afterward the history of the case pointing to early pregnancy, and the sudden occurrence of intense pain, syncope, and collapse will distinguish this condition.

The treatment consists of removal of the affected tube and ovary as soon as the diagnosis is made. In late extrauterine pregnancies it may be necessary, after controlling hemorrhage, to suture the sac-wall to the lower angle of the abdominal incision.—(*Pocket Cyclopedia.*)

(*b*) The following tables (from Dorland's *Obstetrics*) give the main points to be looked for in a *differential diagnosis of extrauterine pregnancy:*

From *cornual pregnancy:*

EXTRAUTERINE PREGNANCY.	CORNUAL PREGNANCY.
Rupture is most prone to take place at some period during the first three months.	Rupture usually occurs between the third and sixth months.
The tumor exists to one or the other side of the uterus, and is usually distinct.	There may be but one tumor, this being dependent upon the degree of bifurcation.
The tumor is exceedingly sensitive and semi-elastic.	The tumor is not so sensitive and presents the characteristics of a uterine tumor.
The round ligament may be felt attached to the uterus on the inner or uterine side of the gestation sac.	The round ligament is displaced outward and is attached to the external side of the gestation sac.
Examination of the removed specimen shows an absence of true decidual tissue.	True decidual tissue will be found surrounding the fetal membranes.
In interstitial pregnancy the gestation sac communicates with the uterine cavity by the orifice of the Fallopian tube.	The two halves of the uterus are united by a muscular band.

From *pyosalpinx:*

EXTRAUTERINE PREGNANCY.	PYOSALPINX WITH INDISTINCT HISTORY OF PREGNANCY.
The uterus is enlarged, with a soft cervix and the peculiar softening of the body that is present in pregnancy.	The uterus is probably not enlarged, the cervix is not soft, and there is not the elastic feel that is present in pregnancy.
There is a history of sterility, with the signs of endometritis or salpingitis.	There is a history of acute attacks of peritonitis occurring at intervals after an attack of gonorrhea.
The tumor is small, exceedingly sensitive, but, as a rule, not firmly bound down in the pelvic cavity.	The tumor is large, moderately sensitive, firmly bound down in the pelvis, and surrounding by a mass of exuded lymph.
Rupture is likely to occur at some time during the first three months.	The history may have covered a period of months without the symptoms of rupture.
The usual clinical manifestations of pregnancy will be present.	The clinical manifestations of pregnancy are absent or very indistinct.

From *intrauterine pregnancy with fibroid tumor:*

EXTRAUTERINE PREGNANCY (TUBAL VARIETY.)	INTRAUTERINE PREGNANCY COMPLICATED WITH FIBROID TUMOR.
There is discovered to one side of the uterus a mass, rounded, exceedingly sensitive, and elastic or semi-fluctuating.	The mass may be rounded; more often it is nodulated, very hard, non-elastic and non-fluctuating, and not sensitive to the touch.
The uterus is enlarged, but not to a size proportionate to the period of gestation.	The size of the uterus corresponds to, or is even in excess of, the time of gestation.
The menstrual history is irregular, and there may be an early return of the show.	Menstruation is likely to be suppressed.
Rupture occurs at the usual time.	No signs of rupture follow.
Pain is an early and prominent symptom.	Pain develops only after the tumor has reached sufficient size to press upon the surrounding structures.

(*c*) The following articles should be taken by the accoucheur to a confinement. Tablets of bichloride of

mercury, or some other material for making antiseptic solution; forceps; ether or chloroform, with inhaler or mask; fluidextract of ergot, hypodermic syringe, with tablets of strychnine, morphine, etc.; needles, sutures, and needle holder; nail brush and nail cleaner; umbilical scissors; carbolized vaseline; stethoscope; male catheter (rubber); a one per cent. solution of nitrate of silver.

10. (*a*) *Care of mother during puerperium: "During the first week* the patient keeps the bed, but after the first few hours she has considerable license. She may assume the sitting or half-sitting posture to take her meals and to nurse the baby, and, if necessary, for evacuation of the bladder and rectum. She should assume the lateroprone posture both right and left, several times a day, and lie upon her abdomen for at least an hour daily. Frequent change of position favors uterine drainage and massages the uterine supports. *During the second week* she has greater liberty, while the greater part of her time is spent on the bed or lounge. She may sit up for her meals, to urinate, and for bowel movements, and she should spend at least half an hour, twice daily, in abdominal and leg exercises to keep up her muscular tone. *The third week* she may be moved to a chair for a part of the day, having the liberty of the room. After sitting up for any length of time she should be instructed to take the genupectoral position before lying down. Prescribed exercises for the legs and abdominal muscles are to be taken daily. *The fourth week*, if all goes well, she may leave the room and have the benefits of air and sun. Physical exercises should be continued. The duration of the lying-in period and the degree of freedom to be given the patient after the second week must, however, depend on the character and amount of the lochia, the general progress of her convalescence, and the rate of the uterine involution."—(Polak's *Obstetrics.*)

(*b.*) *Three most frequent causes of hyperemesis gravidarum:* Toxemia, reflex irritation, neuroses.

SURGERY.

1. *Osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone.

It is *caused* by infection, the bacteria gaining entrance either through a wound, or by extension from neighboring tissues, or they may be brought by the blood.

Symptoms: Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present.

It is to be *diagnosed* from (1) *Rheumatism,* in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tubercular arthritis,* in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis* in which the bone and periosteum are not affected, and in which there is always a wound.

In *osteomyletis,* the *treatment* consists in relieving constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

2. *Intestinal obstruction* may be caused by: Strangulation, kinking, volvulus, foreign bodies, intussusception, stricture, fecal accumulation, and tumors either within or outside the bowel.

STRANGULATION.	INTUSSUSCEPTION.	TWISTS (VOLVULUS)
Subjective Symptoms.	*Subjective symptoms.*	*Subjective Symptoms.*
1. Generally occurs after age of 20.	1. Most frequent in childhood.	1. Most frequent after age of 30.
2. Pain localized, rapid collapse.	2. Constant tenesmus.	2. Pain diffuse.
3. Pain intense, paroxysmal in character.	3. Pain develops suddenly and is continuous.	3. Pain paroxysmal; recurs less often than in strangulation.
4. Constipation complete.	4. Frequent diarrhea, passage of bloody mucus.	4. Constipation complete.
Objective symptoms.	*Objective Symptoms.*	*Objective Symptoms.*
1. Temperature often subnormal.	1. Temperature normal or subnormal.	1. Temperature slightly elevated.
2. Location in small intestine.	2. Localization in small intestine; bowel frequently protrudes at rectum.	2. Location, small intestine; abdomen often protrudes, in certain areas giving dullness on percussion.

—(*Pocket Cyclopedia.*)

And see SYMPTOMATOLOGY, Question 2.

3. CEREBRAL ABSCESS. "The *symptoms* in traumatic cases are acute and, as there is usually diffuse meningitis, there is intense pain, fever, and rigors, coma quickly supervening. In the more common chronic cases the symptoms are often vague in the early stages, but when well marked consist in signs of intracranial pressure. 1. The *headache* and tenderness are severe and localized to the site of the abscess. 2. The *temperature* is subnormal, unless there is associated meningitis. 3. The *pulse* is markedly slowed, even down to 30 or 40. 4. The patient is quite intelligent, but *cerebration* is very slow; vomiting and optic neuritis are usually present. 5. *Motor symptoms* may occur if the abscess is in the anterior part of the temporo-sphenoidal lobe, either irritative or paralytic. If the cerebellum is affected, there is giddiness both while walking and lying down, together with weakness of the hand grip and increase in the knee jerk on the side affected. Lateral nystagmus often occurs.

Diagnosis: From *meningitis,* by the fact that in meningitis there is fever, great restlessness, delirium, photophobia, pain, and spasm in the muscles, especially at the back of the neck. An *extradural abscess* is always accompanied by fever. In *lateral sinus thrombosis* there are rigors and profuse sweats, and there may be a hard tender cord in the situation of the internal jugular vein. Chronic abscess and tumor are often indistinguishable in their symptoms, but the presence of chronic otitis media suggests abscess."—(*Aids to Surgery.*)

4. *Tuberculous abscess.* When the tubercle bacillus attacks a spot there is a surrounding area of chronic inflammation. A combination of action between the bacilli and their products, and the obliteration of the neighboring arterioles by chronic endarteris, brings about liquefaction of the central area. This liquefied material is "tuberculous pus." The process may extend to the surface directly, or, if under deep fascia, spread to a spot far distant. A common example of the latter is a psoas abscess. None of the signs of acute inflammation are present. The wall of the abscess cavity is lined by pulpy, gelatinous-looking granulation tissue containing miliary tubercles.

5. In *fracture of the surgical neck of the humerus,* "the symptoms are pain (which may be reflected along the large nerves from pressure), abnormal mobility, crepitus, shortening of the limb (1 inch or more), a depression just below the shoulder, and abduction of the elbow from the side of the body. The upper end of the lower fragment passes into the axilla, owing to the inward traction of the muscles attached to the bicipital groove (pectoralis major, teres major, latissimus dorsi), and the upward pull of the deltoid, biceps, coracobrachialis, and triceps; the upper fragment may be abducted by the supraspinatus, but there is little or no rotary displacement, because the subscapularis in front and the teres minor and infraspinatus behind nearly or quite balance each other; if impaction be present the signs are obscure and the diagnosis difficult. The deformity resembles that of dislocation of the shoulders, but in the former the depression is lower, the head of the bone is in place, and, when the arm is rotated, there is immobility of the head with crepitus. The *x*-ray should be used in doubtful cases. The complications are injuries of the axillary vessels or nerves, particularly the circumflex nerve, which passes around the bone at or near the line of fracture. The prognosis is good,

but in the old and rheumatic stiffness and pain are frequent legacies."—(Stewart's *Surgery.*)

6. The *symptoms of gallstones* are: "*Indefinite pains;* fullness in right hypochondrium and epigastrium. *Paroxysms of colic* begin in hypochondriac and epigastric regions, spread toward navel and right scapula; generally begin in daytime, during exercise, and last a few minutes to several hours; collapse, sickness, or vomiting. *Sickness and malaise,* quite independent of colic. *Vomiting.*—At end of paroxysm; bile-stained vomit; calculus is rarely vomited. *Collapse.*—Feeble pulse; clammy skin, low temperature. *Calculi in feces.*—Absence in some cases accounted for by stone having failed to reach the intestine. *Jaundice.*—Usually occurs 12 to 36 hours after colic; skin, urine, conjunctiva are yellow; feces are clay colored and offensive; rarely, and in old people, jaundice occurs without preceding colic; does not occur when stone is in cystic duct; is partial, *i.e.* feces contain bile when obstruction is partial, or when fistulous communication exists. *Temperature.*—Sometimes rigors, with temperature 103° or more, occur after colic; probably due to septic infection at seat of ulceration; fever may be of an intermittent type, associated with catarrh of bile-ducts and an impacted calculus; may be remittent, and lead on to septicemia or septic endocarditis; associated with suppuration in bile-ducts."—(*Synopsis of Surgery.*)

And see SYMPTOMATOLOGY, Question 1.

7. The *clinical characteristics of a malignant tumor* are: "It is not encapsulated, it grows rapidly, it infiltrates the surrounding tissues, it often ulcerates, it gives rise to metastatic growths, it has a tendency to recur after excision, causes cachexia, and tends to destroy life.

8. *Tuberculous disease of the shoulder joint.* "This is usually met with in young adults, and is more common in the right shoulder. The prominent features are pain, rigidity, and wasting of the deltoid and scapular muscles. The pain is sometimes severe, shooting down the arm and interfering with sleep, and it may be associated with tenderness on pressure over the upper end of the humerus. In cases with advanced carious destruction of the articular surfaces, there are starting pains and the upper arm is shortened. If a cold abscess forms in the bursa underneath the deltoid, the pus may burrow and appear at the anterior or posterior boundary of the axilla or in the axillary space. Pus formed in the joint tends to gravitate along the bicipital groove. The axillary glands may become infected. The *diagnosis* is to be made from (1) arthritis deformans, in which the movements are less restricted, and are attended with grating and crackling; (2) paralysis involving the deltoid and scapular muscles—by the absence of pain,and the flail-like character of the movements; (3) disease in the sub-deltoid bursa—by the absence of rigidity and other evidence of implication of the articular surfaces; and (4) sarcoma of the upper end of the humerus—by the history of the case, the use of the *x*-rays, or an exploratory incision."—(Thomson and Miles' *Manual of Surgery.*)

9. FRACTURES OF THE UPPER THIRD OF THE FEMUR.—"*Intracapsular fracture* most commonly occurs in people over fifty, especially women, owing to senile changes in the bone rendering it brittle. As a rule, indirect violence is the cause—*e.g.* slipping off a curb or catching the toe in a carpet. The patient falls, and is unable to walk or raise the limb. The head may be held at first by the retinacular fibres. If impaction, which is uncommon, occurs, the neck is driven into the head. The displacement consists of drawing up of the lower fragment and external rotation. The rotation is due to the weight of the limb and to greater breaking up of the posterior surface than of the anterior. Shortening is rarely more than three-quarters of an inch. Treatment.—Fibrous union nearly always occurs in old people, as the blood supply of the upper fragment depends solely on the obturator branch running in the ligamentum teres. Then, old people often die of hypostatic pneumonia if kept lying long upon the back. If the patient be young, he should be put upon a long Liston splint, with extension, for six weeks. The same should be tried with old people, but the moment the respirations begin to increase the patient must be got up, wearing a Thomas's hip splint. Impaction favors bony union, and so should not be broken down.

"*Extracapsular fracture* means fracture of the neck near the trochanter, and often is associated with splitting up of the trochanter. The usual cause is a heavy fall on the great trochanter, and impaction is common. Shortening always occurs, up to a much as 3 inches; external rotation of the limb is always present, and if there is impaction the trochanter is broadened.

"*Signs and Symptoms of Fractures of the Neck.*—1. Pain, bruising, and swelling are more marked in extracapsular fractures. 2. Crepitus is present in the unimpacted fractures. 3. Loss of power usually occurs in both, but patients have walked with impacted fractures. 4. Eversion is a striking feature in both. 5. Shortening is much more marked in extracapsular fractures. 6. The position of the great trochanter is altered. It is raised, everted, nearer to the mid-line, and rotates in the arc of a smaller circle than the opposite one.

Its position is demonstrated as follows: *Néalton's line* is drawn from the anterior superior iliac spine to the tuber ischii. The top of the trochanter should touch this line if the limb is placed in the axis of the body. *Bryant's line:* Drop a vertical line to the bed from the anterior superior spine, and measure off the length of a line running at right angles from this to the trochanter, and compare it with a similar line on the sound side. *Morris's bitrochanteric test:* Measure and compare the distances of the trochanter from the mid-line. 7. Broadening of the trochanter only occurs in extracapsular fracture. *Treatment.* Unless there is great deformity, it is not advisable to break up impaction. Bony union always occurs. The patient should be anesthetized, and traction kept upon the leg during fixation. A stirrup extension is first put on, and then the leg is firmly bandaged to a long Liston splint, with the eversion corrected. The chest is fixed to the splint by a binder; the foot of the bed is raised, and a weight of 8 or 10 pounds is put on to the cord of the stirrup extension. Hodgen's splint may also be used. Union occurs in six weeks.

"*Fracture of the great trochanter* without fracture of the neck is very rare. If the fragment is displaced, it should be wired or pegged.

"*Separation of the epiphysis* of the head of the femur resembles intracapsular fracture. Impairment of growth may follow.

"*Fractures of the shaft of the femur* may be due to either direct or indirect violence. The displacement varies according to the situation and obliquity of the fracture. In the *upper third* the upper fragment is flexed, abducted, and rotated out by the psoas, iliacus, and glutei, while the lower is drawn up and adducted by the adductors, and rotated out by its own weight."—(*Aids to Surgery.*)

10. *Congenital club-foot.*—By club-foot is meant a deformity of the foot due to muscular, ligamentous, or osseous causes, the displacement occurring mainly at the ankle and mid-tarsal joints. It may be congenital or acquired. *Congenital malformation* is responsible for a certain percentage of the cases, resulting from imperfect formation of the bones of the foot, occasionally from absence of the lower end of the tibia or fibula, or very rarely from intra-uterine paralysis of central origin. Other cases are due to malposition of the feet in utero, possibly resulting from a deficient amount of liquor amnii, as a result of which the feet are abnormally compressed and held in one position. Naturally the legs of the fetus are in a state of flexion, and the feet usually in a position corresponding to that of talipes varus; it is easy then to understand that in an unusually small uterus this position may become fixed. Spinal bifida in the lumbar region is occasionally associated with congenital talipes, which is then probably due to impairment of nervous control. The congenital variety is often hereditary, and may occur in several members of the same family, or be transmitted through many generations.—(From Rose and Carless' *Surgery.*)

Gas Phlegmon.—Rumpel on the German Western front saw 160 cases of gas phlegmon in 1200 wounded, mortality 50 per cent. There has been no progress in treatment but a preventive serum appears able to reduce the mortality to 6 per cent.—*Office International d'Hygiène Publique.*

THE WAX-MODELING DEPARTMENT OF THE ARMY MEDICAL MUSEUM OF THE SURGEON-GENERAL'S OFFICE, AND THE APPLICATION OF THE ART TO GENERAL MEDICINE.

BY MAJOR R. W. SHUFELDT, C.M.Z.S.,
MEDICAL CORPS, U. S. ARMY,
ARMY MEDICAL MUSEUM.
WASHINGTON, D. C.

WHEN we come to regard as a whole all of the various branches and specialties that go to form the one great common science encompassed by the terms medicine and surgery, it will be noted that this branch of human learning has, up to the present time, enlisted in its service or invoked the aid of the major part of the achievements of nearly every department of research which man has entered upon. This thoroughly justifiable species of appropriation has long been evident with respect to the mechanic arts, wherein the surgeon has utilized, in one way or another, hundreds of the most ingenious creations of the inventors comprised in the various departments that go to make up that heterogeneous combination of industries. In untold numbers of inventions, employed by the surgeon in his profession, we see the application and adaptation of every principle known to ancient and modern physics—as the lever, the wedge, the screw, and the rest; while in the fields of matter, force, and motion, as exemplified by those laws which we designate as gravitation, hydrodynamics, gases, acoustics, heat, light, electricity, and meteorology, there is not one that the practitioner of modern surgery is not more or less indebted to for the measure of his various successes. All of the mechanical contrivances he employs rest, in one way or another, in some one of these sciences, and surely there is a very large number of them.

So, too, with the various equipments employed in photography, in pictorial work, in the fine arts, and in biology in its broadest sense.

Of all these we have but to invite attention to one in the present article, and this pertains to an art rather than to an exact science, although some of the elements of scientific requirements enter into it. Aside from what photography or any line of pictorial achievement can do for him, the surgeon, the specialist, or the general practitioner of medicine

FIG. 1.—Captain James Frank Wallis, M.C., U. S. Army. Modeling Department, Army Medical Museum.

FIG. 2.—Miss Eleanor Courtenay Allen. Modeling Department, Army Medical Museum.

frequently desires, for many reasons, to give material expression to what those callings bring before him in the line of his work. For example, we may have the arm of a man presenting all of the characteristic ravages of tertiary syphilis; however

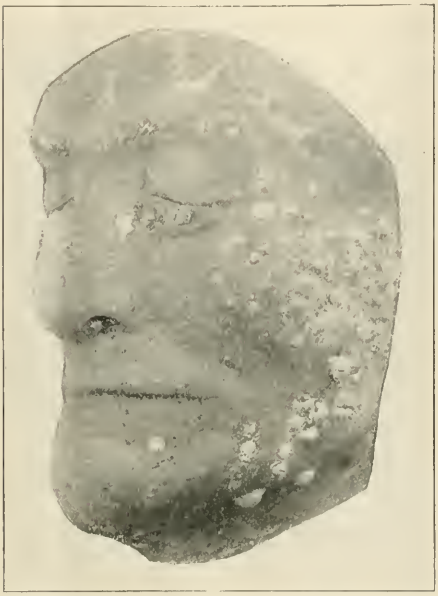

Fig. 3.—Left oblique view of face. Baretta model. Army Medical Museum. 9840. Wax. Sebaceous epithelioma or cancrodial acne. Æt. 67. 12 years' duration.

vividly the syphilographer may describe this case, it will ever lack what accurate visual manifestation can do for it. To be sure, it may be photographed and colored, or pictorially illustrated in other ways; but in all of these we lack the advantage of rotundity, associated with accurate coloring. Here is where the art of the modeler in wax comes in, with his ability to reproduce the actual color of the pathological condition he desires to preserve in the form of a model having the exact contour of the original.

When the awakening of the old Army Medical Museum of the Surgeon General's Office took place, due to the stimulation engendered by the present war, Colonel Wm. O. Owen, the officer in charge of that institution, was quick to perceive the necessity for preserving, through the art of wax modeling, various pathological conditions that would be exemplified in man and in the lower animals, which might in time, after the conflict, be quite unfamiliar to the coming generations of physicians and surgeons.

The Army Medical Museum already possesses quite a large collection of the J. Baretta wax models, secured many years ago; both Baretta and Mons. Tramond were celebrated workers in this art in Paris during the last century. The models we have of the first-named expert are, as a rule, of skin diseases, including the venereal ones; they are exhibited in table-cases on the main museum floor, and a number of them have been injured through having been exposed to the direct rays of the sun. Some of this damage has lately been repaired through the skill of Miss Eleanor Courtenay Allen, whose work will be illustrated further on in this article.

During the early summer of 1918 the department in question began to assume the unmistakable evidences of an awakening, and some remarkable results in the way of wax models passed into the temporary cases of Series "B," which is the great war series. Fortunate it was that the Medical Department secured the services of Captain J. Frank Wallis, of the Medical Corps, for not only is he a finished modeler in wax, but a teacher, and a well-known author in dermatology and allied branches of medicine. (Fig. 1.)*

In this section of the Museum is also attached,

*Commissioned 1st Lieut. M. R. C. Aug. 30, 1917. Capt. June, 1918. Graduate in Pharmacy, 1889, Univ. Penn., 1895. Dermatologist to Southern Dispensary, Phila., 1896-1910. Instr. in Dermatology, Post-Grad.

women are so natural that they, when draped, have

*Miss Allen designed and taught drawing in the public schools of Wisconsin for one year. She then went to Milwaukee Public Museum as wax modeler, remaining there four years. The first models she made were of fleshy fungi, both the edible and poisonous varieties, for exhibition to the public as means of identification of the various species. Fifty groups of these mushrooms are to be seen at the museum, shown in their natural habitat. She did the collecting of these specimens and the material for their habitat. In assembling them, she grouped the wax mushrooms in surroundings to simulate the natural. She also made a

Fig. 6.—Polydactylism. Child seven months old; girl. Description in text.

large diagrammatic model of the *Amanita phalloides*, giving a cross section to show the structure of the plant. While at this museum she made wax models of batrachians, showing the following groups of frogs in their natural environment in various positions: leopard, pickerel, and green. She also made fish models in wax and colored them. A collection of wax models made by her showing four mushrooms and a human hand have been placed on exhibition in the Smithsonian Institution at Washington, D. C. During her four years at the Milwaukee Public Museum she made, in her spare time, some pathological models at the suggestion of a Chicago surgeon. Dr. Edward H. Ochsner, and in 1915 she exhibited these models at a monthly meeting of the

Chicago Surgical Society. Miss Allen came to the Army Medical Museum and began work on March 13, 1918, making pathological models exclusively, and she considers this to be her best line of work. She is now serving in France, and obtaining models for the Museum.

all the appearances of belonging to living individuals.

Few realize that the art of wax modeling dates back to Lysistratus, who flourished about 300 B.C. He devoted himself largely to the human face, taking his molds in plaster. These colored busts were used by the ancient Romans as evidences of nobility, and were exhibited in the vestibules of their homes. Much later, that is, in the 18th century, Ercole Lelli and Giovanni Manzoli brought fame to the Institute of Bologna through their contributions of anatomical wax models of its collections, while Susini and Fontana did the same for Florence by filling no fewer than fifteen chambers with a superb array of anatomical models in wax. As we pass to modern

Fig. 9.—Anterior aspect of right thigh. Self-mutilation, followed by eruption of Eczema traumatica. History of case in text. Wallis model.

times, we find many such collections in the museums of both Europe and America. It is truly remarkable to note the morbid interest taken in such displays by the visiting lay public; but, upon the other hand, to the student of dermatology and many of the superficial pathological conditions, they are often invaluable.

At present there is a large literature upon this subject, and astounding advances have been made in every line of the technique of the art in recent years. This not only consists in the making of the actual model, but also in the coloring process and the mode of exhibition. This history is altogether too extensive to even pass briefly in review in the present connection. What chiefly interests us here is the fact that we have, at the Army Medical Museum, actively and continuously at work during the regular government hours, two such masters of this art as Miss Allen and Captain Wallis, and that they are producing magnificent finished models, colored to life, of many superficial conditions, a number of which—as mustard gas poisoning and so on—are incidental to the present war. These will be described in the forthcoming medical and surgical history of this war, and the originals exhibited in the Army Medical Museum, for the study of every one interested in the years to come.*

The photographs of these models were made by Mr. Roy Reeve and his assistants in the galleries of the Army Medical Museum, which is a guaranty of their accuracy and merit. The face of the case shown in Fig. 3 is that of a farmer whose sister had the same disease—a malignant cancroidal acne. The cast is of the left and part of the right side of the face, exhibiting this sebaceous epithelioma in every stage of its development. There is a large ulcer on the right side of the nose, which shows only in part in the illustration. It will be noted that numerous patches of incipient epithelial acne cover a good part of the face. There are also patches of the second degree and horn-like vegetations on the left side of the forehead, which are red, excoriated, and papillomatous; an epithelial ulcer on the lower eyelid of the left eye, and other pathological states diagnostic of this disease. This man had a brother who died at 75 years of age; he had "crusts" on the body. One sister had spots like the patient, the latter having been admitted to the St. Louis Hospital, Paris, in November 13, 1886, and left six days thereafter. The disease began as small, yellow spots in 1874, and in 1882 the largest, on the right side of the nose, commenced to ulcerate; by 1886 it appeared as in the model. In 1883 a second group of ulcerations appeared on the lower eyelid.

In Figure 4 Captain Wallis has given us a model showing a typical case of "Dermatitis venenata" (*Rhus venenata*), the subject being a school boy sixteen years of age. I have been furnished with the following record of the case: "One of twelve

*There is an excellent article on "Wax Models of Unusual Types of Skin Diseases" (Figs. 1-4) in the *Transactions of the Section on Cutaneous Medicine and Surgery* of the A. M. A. (53d Ann. Meeting, 1902), by Captain Wallis (pp. 183-188) which is well worthy of study. At the time of its reading it was discussed by Dr. W. S. Gottheil of New York City, who said that "Having done work of this kind myself, I am in a position to appreciate the very great amount of patience and skill that is required to make these models. Nothing in the way of a photograph or painting, and still less anything in the way of verbal description, can approach it as a means of recording skin lesions. It is not possible, however, for a practitioner to devote to it the time that is required; and until we have some one like Baretta of Paris here, it can only serve as an occasional means of record in the hands of younger and artistically inclined dermatologists." (P. 188.) The art of wax modeling, and how these models are colored true to life, is quite fully treated in another article by Captain Wallis, entitled "Exhibit of Wax Models of Cutaneous Diseases, with Remarks Upon the Uses of Wax Models and Their Preparation," published in connection with Dr. Jay F. Schamberg. Trans. Coll. Phys. of Phila., 3r scr., Vol. 23, Phila., 1901, pp. 36-41. Discussed by Dr. James K. Young and Dr. Schamberg. This article is deserving of very careful study by the art student in this department of the fine arts.

boys used the wood of poison sumach to make arrows. All became severely involved, the eruption appearing upon the hands, face, arms, legs, and pubic region. One boy used his teeth to remove the bark, and suffered with intense involvement of mucous membrane of the mouth and throat. Brothers and sisters of the boys playing with the arrows became subject to the eruption. Model represents the first twenty-four hours after exposure to the poison. Twelve hours later the hands became greatly swollen; blebs became confluent. The face suffered much disfigurement; the eyes became closed for two days. Solution of hyposulphite of soda (*sodium thiosulphate*) afforded the greatest relief when applied as a wet compress."

Fig. 10.—Same patient referred to in Fig. 9. Photo. from life. Case in text.

Fig. 12.—Right foot showing eczema papillaris. Baretta wax model 22. Army Med. Mus. No. 9794. Case in text.

In Figure 5 we have one of the finest pieces of work that Miss Allen has turned out since she came into this department, and it has received the unqualified praise of a great many experts who have seen it. It is a wax model of the right hand of a boy eleven years old, exhibiting a case of nævus unius lateris; he was treated by Dr. H. H. Hazen, of Washington, D. C. The disease is seen to extend below the thumb, and it lasted for seven years. This cut gives one but a very indifferent idea of the wonders of this model. Every detail of the skin and the disease is reproduced in the most minute manner, and the coloring is perfect. The nails so closely resemble the originals as to be distinguished with difficulty when the hand is covered with a cloth. It is truly a marvelous piece of work.

The hands of the baby shown in Figure 6 are also by Miss Allen, and they are quite equal to the one reproduced in Fig. 5. The subject was a male child, seven weeks old, and both hands are seen to be polydactylous. There are two complete thumbs on the right hand, with bones and nails. In the case of the left hand, the three thumbs present are all fused into one pollex. One of these thumbs is complete on its lateral aspect, and two medial thumbs are composed of one metacarpal bone and four phalanges. On March 23, 1918, Major R. Tunstall Taylor, M. C., Department of Orthopedics (Army Medical Museum), removed the supernumerary thumb at his clinic at the Kernan Hospital, Baltimore, Md. This beautiful model is now on exhibition at the Museum, where it was photographed.

The case of syndactylism seen in Figure 7 is another fine model in the collection. The patient, a male, was born in Indianapolis, Indiana, on July 13, 1881, and now resides at Washington, D. C. This model is likewise on exhibition at the Army Medical Museum.

An extraordinary case is shown in Fig. 8, it being that of a female child seven years of age. There is a congenital absence of all the thumb bones of the radius (Allen model), and the specimen is also in our collection. An *x*-ray has been made of it for the series in the Museum; and in the motion-picture room it may be thrown on the screen for the purpose of demonstrating the uses of this deformed member, which, curiously enough, are of very wide range.

An interesting case is shown in Figures 9 and 10, the limb having been faithfully modeled by Captain Wallis. In Figure 9 we have "eczema traumatica" following upon self-mutilation, incited by religious mania. Some of the marks are crosses, others the letters I. H. S., etc. Captain Wallis has kindly furnished me with the following abstract of this patient from the records of St. Elizabeth's Hospital for the Insane, at Washington, D. C. (Case 17,891), where it is recorded in even greater detail. (May 16, 1918.)

J. F., 53 years of age, an ex-soldier who has served three enlistments. Had paralysis of the legs in 1904 or 1905, after which symptoms pointing to mental disturbances appeared. He imagined everybody was after him and intended to injure or kill him. He was generally depressed and heard voices. Numerous old cutaneous scars and scratches all over his body, self-inflicted. Some of the scratches spell the words "Jesus" and "Wah Wah." There are also numerous scars on the body. Muscles of the lower extremities show slight wasting. When given a bible, he tears the leaves out and sticks them on his chest, or he chews them up and swallows them. Patient is fairly well informed in current events; oriented in all spheres, and takes a certain amount of interest in his surroundings. No explanation of the cause of this mutilation can be obtained from the patient; they are in all probability self-crucifixion symbols."*

An excellent example of "mustard gas poisoning" is shown in Figure 11 (Allen model); it is colored true to life, and has been studied by many military and civil surgeons visiting the museum. Captain Wallis furnishes me with the following history:

Civilian experimental chemist, 24 years old, March 9, 1918. During the course of experiments a container broke and scattered its contents over this man. He immediately washed the exposed surfaces of the body, but did not remove the clothing covering his leg. There was a lapse of two hours between time of accident and removal of clothes at bedtime. Local symptoms of burns, with development of large vesicles, appeared about 16 hours after onset. He was immediately removed to hospital, and has been in bed since. Treatment: 25 per cent. magnesium sulphate dressing. Hot fomentation and ambrine. Emergency Hospital, Washington, D. C.

Finally, I desire to present still another example of Baretta's marvelous work, it being a case of papillary eruptions, following upon an eczema on the dorsum of the right foot of a white patient. It is from the service of Doctor Bazin of Paris and one of the most conspicuous pieces in the collection of the Army Medical Museum. No better example could be produced presenting the sequelæ of an eczema papillaris in the advanced stages of the disease. The model is in an excellent state of preservation, and a very interesting one for the student of dermatology to consider.

As a matter of fact, the collection of wax models of skin disease and other dermal and topographical pathologies in the cases of the Army Medical Museum are well worthy of a day's study and examination on the part of any medical practitioner in whose practice occurs any of the diseases so graphically represented by the many models. Moreover, it is most gratifying to know that the collection is once more being augmented by additions made to it by such competent workers as those who have been named in this brief account of their very satisfactory achievements in this important department of medical museology.

*Captain Wallis in this model has introduced a new method of mounting. It does away, as will be seen in the cut, with the surrounding white muslin material, and so firmly fixes the model on its black stand or base that no amount of jarring or handling can possibly loosen it. This is effected by fastening linen strips in the wax on the under side, embedded so thoroughly that they cannot be pulled out. Then, opposite them, on the board base, are slits cut clean through, which allow these strips to be pulled through to the other or under side, and made taut, fastening them finally with big thumb-tacks of nickel or brass. These hold the model firmly to its wooden base—at the same time it can be readily removed at any time for repair or other purpose by simply pulling out the aforesaid tacks.

Diphtheria Antitoxin in Nondiphtheritic Anginas.—The fact that membranous sore throats proved not to be diphtheritic show remarkable improvement at times after injections of antitoxin has often been noted, but its use in such cases has never been encouraged. Two Spanish practitioners, however, have written a paper on the subject reporting a long series of favorable cases. The indications are any angina accompanied by adenopathy and a temperature of 38-39°.—*Brazil Médico.*

HISTOGENESIS AND PATHOLOGY OF SUBDURAL HEMORRHAGES.*

By G. B. HASSIN, M.D.,

CHICAGO.

ATTENDING NEUROLOGIST TO THE COOK COUNTY HOSPITAL.

A SUBDURAL hemorrhage or hematoma of the dura has been considered since Virchow's time as a form of "inflammation" of the dura, as an "internal hemorrhagic pachymeningitis." Virchow[1] looked upon the hemorrhage as the product of the inflamed dura in which first of all a pseudomembrane forms exceedingly rich in blood vessels, the rupture of the latter causing a hemorrhage which thus, according to Virchow, is always a secondary process. Since accumulation of blood in the subdural or subarachnoid spaces is frequently found after head injuries, obstetrical deliveries, surgical brain operations, where thus an inflammatory process of any kind can be excluded, it became customary to designate such subdural hemorrhages as traumatic or meningeal. The latter, according to some authors as Jores,[2] Van Vleuten,[3] Laurant,[4] have nothing to do with the hematoma of the dura differing from same histologically and pathologically, though Laurant admits that "cases do occur which show a correlation of both types."

As this is not the place for detailed discussions of various theories and types of hemorrhagic pachymeningitis, I shall merely point out the fact that some of the latest investigators, as Pierre Marie, Roussy, and Laroche,[5] differentiate as many as nine types, including several subtypes, of this morbid condition, and like Virchow they come to the conclusion that whatever the type there is always present an inflammation of the dura, the hemorrhage being its ultimate product.

As can be gathered from the recent statistics by Ciarla,[6] the most frequent type of hemorrhagic pachymeningitis is that of subdural hemorrhage, in the form of a blood clot covering usually the convexity of the brain, rarely the base. In some cases a hematoma is absent, being replaced by hemorrhagic small foci or thin, rusty membranes on the inner surface of the dura (Ford Robertson).[7] In other cases the blood is enclosed within a connective tissue sack when it is spoken of as a subarachnoid cyst, and again cases occur in which neither hematoma nor bloody cysts are found, but merely a thickened membrane consisting of several pseudomembranes. The dura in such cases may appear enormously thickened, consisting of as many as twenty pseudomembranes (Virchow). Such cases are referred to as idiopathic pachymeningitis,[8] and like the previous two forms are looked upon as a morbid condition of the dura, as the result of its inflammation.

From the histopathological studies of these principal types of pachymeningitis—hematoma of the dura, arachnoid cyst, and pachymeningitis proper—I came to the conclusion that *neither form has anything to do with the dura, that in none of them an inflammation of this membrane is to be found, and that the principal, the most striking, changes are confined to the pia-arachnoid.* The difference in the pathological findings, in some cases hemorrhages, in others cysts or mere thickening of the membranes, is due to the etiological factors which, in the form of acute infections or head injuries, are responsible for the subdural hemorrhages with or without cyst formation, or in the form of chronic infection, mostly syphilis, are productive of the third variety, pachymeningitis proper. As space would not permit of a detailed discussion of all my cases, I will confine myself in this contributon to the description of hematoma and subdural cyst only.

The third type will be taken up in a separate contribution.[16]

CASE I.—Man, apparently 35 yrs. old, of small stature, was brought June 26th, 1917, unconscious to the Cook County Hospital, the medical service of Dr. Post, with a police record of having been ill 24 hours. The respiration was of Cheyne-Stokes type, the temperature 99.4°, pulse 26. The patient's head was drawn slightly to the right and backwards, the eyes were turned to the

FIG. 1.—Case 1. The pia from a case of subdural hemorrhage. It fills up a sulcus between two cerebral convolutions (B). A, A, thrombosed arteries; c, c, c, distended meshes of pia connective tissue; d, infiltration cells, explained in text; VI, a vein; VII, a ruptured vein; Ar., arachnoid membrane. Van Gieson stain. Magnification, 40.

right, and the neck was rigid. The pupils were small, reacted to light and in accommodation. The tendon reflexes were quite lively, without a Babinski, but there was a positive Kernig, and also a positive abdominal reflex. The blood pressure was 140 systolic, 100 diastolic, the heart and lungs showed at the first examination no marked changes. The spinal puncture gave a clear fluid under increased pressure with 37 polynuclears, 13 lymphocytes, a negative Nonne and Wassermann. The latter was also negative in the blood. Subsequent spinal punctures revealed a slightly turbid fluid containing red cells, polynuclears, and lymphocytes, as well as intra- and extracellular diplococci. The urine contained pus cells, granular casts, and albumin. The next day, the lung examination showed bronchial breathing, rales, and effusion in the pleural cavity. Four ounces of clear fluid were withdrawn from the pleural cavity, containing polymorphonuclears and lymphocytes.

Seven days after his entrance to the hospital the patient died and the post mortem performed on the day of his death showed "a hemorrhagic internal pachymeningitis, a bilateral bronchopneumonia, mucopurulent tracheo-bronchitis, multiple disseminated petechial hemorrhages in the gastric mucosa, and cloudy swelling of the kidneys."

The right cerebral hemisphere was covered with a

*From the pathological laboratory of Cook County Hospital.

bloody clot which in its shape resembled the configuration of the hemisphere. The blood clot covered the frontoparietal region of the brain and was easily detachable from the dura, *i.e.* there were no adhesions present. The inner surface of the dura appeared very bloody, somewhat thickened, and the longitudinal sinus was totally thrombosed. The brain itself was apparently normal, while the pia-arachnoid, on the right, showed largely distended veins and appeared opaque on the left.

Sections (celloidin and frozen) were made from the coagulum, dura, the brain tissue including the pia-arachnoid, and stained with hematoxylin-eosin, methylblue eosin, Weigert's elastica stain, Van Gieson, and toluidin-blue.

The examination of the blood clot showed two thin, young connective-tissue membranes enclosing a coagulated mass that consisted of a great number of distended and hyperemic capillaries scattered over thick meshes of fibrin. The latter were very dense and contained numerous red cells mixed with fibroblasts, polyblasts, machrophags, and gitter cells. The fibroblasts and macrophags were packed with granules and globules of pigment which was also freely scattered among the above mentioned cellular elements. The walls of the coagulum mainly consisted of fibroblasts that contained large chromatin-rich nuclei.

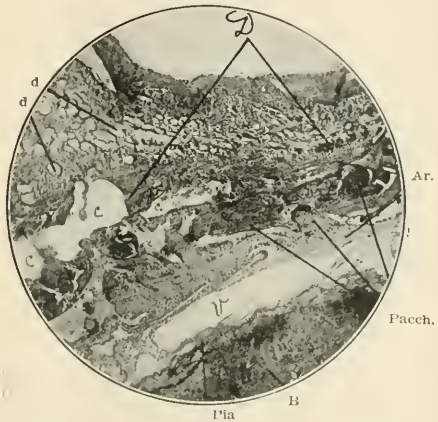

FIG. 2.—Case I. D, dura mater with numerous lacunæ (d) and distended interspaces (c). Ar., the arachnoid membrane with Pacchionian (Pacch.) bodies and small hemorrhages; the pia exhibits distended veins (v); B, brain tissue. Van Gieson stain. Magnification, 26.

In short, the coagulum appeared as a young connective-tissue membrane undergoing the process of organization. Any adhesions between the coagulum and the dura or pia were totally absent. The examination of the dura itself revealed the usual structure of this membrane, namely, collagen fibers forming bundles crossing and recrossing each other, depending upon the layer of the dura, and separated by free interspaces, or grooves, of various shapes and sizes. The middle layer of the dura usually showed a great many round and oval spaces, so-called lacunæ, which gave the membrane an areolar or cribriform appearance. The lacunæ like the interspaces were as a rule empty, *i.e.* free from any contents, as blood, pigment, or fibrin, though the interspaces sometimes showed the presence of some blood. Any cellular elements, except the so-called dura nuclei of large rod-like shape, were absent from the dura, but pigment in more or less large amount could be occasionally found even in the most superficial layers of this membrane. However, the inner layer adjacent to the effused blood was very rich in various cells, as red corpuscles, mast-cells, fibroblasts, and macrophags. The fibroblasts and the macrophags were packed with blood pigment, being in some sections the sole cellular element that could be found in the dura tissue.

Vessels and capillaries were richly represented all over the dura, were usually much distended and hyperemic, especially in the inner layer. Yet even here, in the inner layer, *inflammatory signs*, as fibrin exudation, plasma cells, polyblasts, perivascular cellular infiltrations, *were totally lacking*.

The pia-arachnoid showed changes much more striking. As the microphotograph shows (Fig. 1), these membranes exhibit greatly distended meshes of connective tissue, numerous cellular elements (*d*) and greatly hyperemic, distended vessels, especially veins and capillaries. At *V*, Fig. 1, a ruptured distended vein can be plainly seen, and the flooding of the surrounding regions by blood can be noted. In such places, of course, no other elements except red cells are present, but farther away various modified lymphocytes, as polyblasts, plasma cells, fibroblasts and macrophags are to be found in large numbers. All inflammatory phenomena are here, as in the dura, totally lacking while various vascular changes in the form of excessive hyperemia, hemorraghes, cellular infiltrations of the connective-tissue meshes, etc., are here very much in evidence. Comparing the conditions of the pia with that of the dura (Fig. 2), one can plainly see the difference in the histological structure. The dura shows a great number of lacunæ (d) free from any contents, a mass of bundles of collagen fibers with their interspaces, some of which, but very few, show the presence of blood, but a complete absence of vascular, infiltrative, or other changes that would indicate the presence of any inflammatory condition in this membrane.

On the same photomicrogram the arachnoid with its Pacchionian bodies is plainly shown without any pathological changes except a few points of hemorrhage. The pia and the adjacent brain tissue, however, are densely infiltrated and exhibit large hemorrhagic foci.

The findings in the dura and the pia-arachnoid can be interpreted as follows: A hemorrhage occurred in the pia from a ruptured vein that led to formation of a coagulum between the dura and the pia, *i.e.* in the subarachnoid space. The organization of the coagulum into a connective-tissue membrane was combined with the process of cleaning up of the bloody membrane of blood, pigment, etc. The cleaning process was especially active in the pia and in the blood clot, but was very little in evidence in the dura, and was carried on by the macrophags, fibroblasts, and gittercells. Had the patient lived long enough, the coagulum would have been totally organized, the damage caused by the hemorrhage would have been repaired, and a new membrane would have been formed attached to and completely resembling the dura. The histopathological findings in this case leave no doubt whatever that the blood clot originated from a ruptured pial vein, that an embryonic connective tissue membrane was in the process of development, with the possible ultimate formation of a pseudo membrane typical of socalled idiopathic pachymeningitis.

That such a histogenesis actually does take place was proven experimentally by Sperling[8] in Leyden's clinic.

Sperling injected rabbits between the dura and arachnoid over the brain vortex with fresh incoagulable rabbit blood. Eight days later the injected blood was found forming itself into a connective-tissue membrane which was completely organized two or three weeks later. By that time newly formed vessels could be demonstrated. The newly formed membranes wholly resembled those found in human hemorrhagic pachymeningitis. They were on the inner surface of the dura and not adherent to the brain tissue.

As defibrinated blood failed to produce a new membrane, Sperling concludes that the formation

of the new membrane was due to the fibrin. Injections of irritating fluids, such as acetic acid, iodine, sodium chlorate solution, did not lead to new membrane formation, but merely produced a thickening or edema of the dura or, when the material was too irritating, its suppuration.

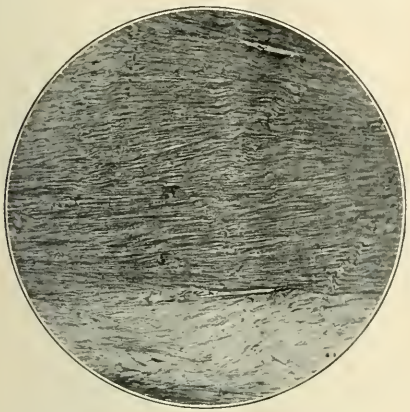

Fig. 3.—Horizontal (surface) section from the inner layer of dura; from a case of subarachnoid cyst. Total absence of hemorrhagic and inflammatory foci. Van Gieson stain. Magnification, 40.

In contrast to Sperling's findings, Marie, Roussy, and Laroche,[5] experimenting in a similar manner on dogs and rabbits, obtained negative results from subdural injections of blood, but when irritating substances were used, like fatty acids, sodium nucleinate, or staphylococci, they succeeded in producing a pachymeningitis. Aseptic blood, free from microbian or chemical irritants, failed to produce a pachymeningitis. Still more significant are the statements of Van Vleuten, who produced experimentally pachymeningitis by bleeding the pia (14 days after the injury of the latter) or by mere trephining.

Entirely contradictory findings are recorded by Boeckman.[10] He tried to determine whether a pachymeningitis is to be found in patients operated upon for various brain lesions, such as tumors. As such operations are invariably accompanied by subdural hemorrhages a pachymeningitis could be expected to form as the result of these hemorrhages. Yet in none of the 57 brains he examined for this purpose could Boeckman find any signs of pachymeningitis, notwithstanding the fact that plenty of time had elapsed between the operation and the death of the patients for a membrane to form. Hence he concludes that trauma causing a rupture of brain vessels cannot produce a pachymeningitis provided he adds that the patient is "constitutionally" healthy.

If this contention be correct, as well as that of Marie and his colaborators, namely that aseptic blood is not able to form a new membrane, we might admit this fact to be true for Sperling's experiments. As he experimented in 1871, in the pre-aseptic era, it is possible that the blood he injected was not wholly aseptic.

In my case the subdural blood clot was possibly rendered septic by the diplococcus infection of the patient's spinal fluid. The latter mixed with the blood furnished by the ruptured pial vessel was a favorable medium, as it were, for the organization of a pseudomembrane and formation of a pachymeningitis.

Equally significant and instructive are the findings in the second case, that of a subarachnoid cyst, a more advanced type of pachymeningitis than the one previously described.

Case II.—White woman, 63 years old, a tailoress by occupation, was admitted Sept. 29, 1917, to Cook County Hospital in the medical service of Dr. W. Butler. As the patient appeared mentally dull, disoriented as to time, place, and persons, a satisfactory history could not be obtained. The patient refused to talk, complaining of severe headache and vomiting. She had a fall on her head, "some time ago," swollen feet for 3 or 4 years, and a year previously some generalized skin eruption. The examination revealed rigidity of the upper and lower limbs, as well as of the abdomen that was covered with petechiæ. The left lower face was drooping, the tendon reflexes were markedly exaggerated with a right ankle clonus, a bilateral patellar clonus, negative Babinski, and normal pupillary reaction. The chest revealed a pulmonary emphysema, indistinct heart sounds, without murmurs. The blood pressure was 140 systolic, 80 diastolic. On spinal puncture the fluid was found to be under greatly increased pressure, contained about 20 cells per cubic millimeter, gave negative Nonne, Noguchi, and Wassermann reactions.

The patient became comatose, cyanotic, the respiration assumed the Cheyne-Stokes type, and a week after admittance to the hospital she died.

The post mortem records show: "Internal hemorrhagic pachymeningitis, free blood in the subdural space, marked compression of the right cerebral cortex, nodular syphilitic (?) aortitis, multiple subcapsular miliary gummata of the liver, slight diffuse chronic nephritis, passive hyperemia of the lungs, latent apical fibrous tuberculosis, focal adhesions of pleura, cholelithiasis."

Further examination of the dura showed its inner surface on both sides covered with bloody masses. On the right side the blood was enclosed within a sack of connective tissue; on the left the sack was torn leaving two bloody, rusty looking connective-tissue membranes.

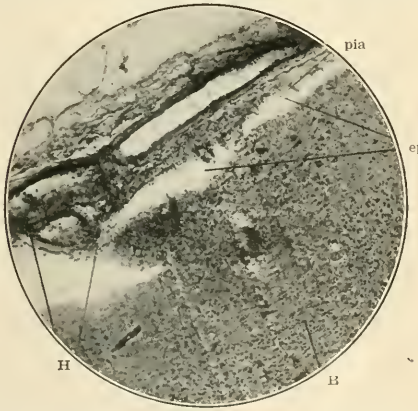

Fig. 4.—Pia and brain tissue in a case of a subarachnoid cyst. Pia, distended containing three veins; two of them are at H, surrounded by hemorrhages; ep, epicerebral space, between the pia and brain; B, brain tissue covered with numerous distended veins and capillaries. Magnification, 70 diameters. Hematoxylin-eosin stain.

The inner membrane adjacent to the cerebral surface was quite thick, loosely hanging on the dura which was covered by another membrane very thin and friable. It could be easily separated from the dura which revealed a clean shiny surface free from any blood clots. These two membranes evidently represent the walls of a cyst

that was torn during the removal of the brain from the skull cavity. On the right side, however, a distinct cyst could be plainly seen covering the inner surface of the dura corresponding to the frontoparietal region of the brain. Frozen surface sections were made from each pseudomembrane, from the inner and external layers of the dura, and stained with the previously mentioned methods. In addition, various portions of the brain, including the pia-arachnoid, were hardened in alcohol, imbedded in celloidin and stained with toluidin-blue. The inner pseudomembrane showed an enormous number of hemorrhages which in some sections covered the entire visual field. As a rule, however, they were intermingled with a great many capillaries, which were much congested, dilated, and surrounded by strands of connective-tissue fibers that sometimes formed a distinct adventitial layer. The spaces between the capillaries not obscured by hemorrhages were filled with various mononuclear elements in which macrophags and polyblasts predominated. The macrophags contained smaller or larger granules of pigment which was also abundantly present outside the cells. Some macrophags were so densely packed with the pigment that no nucleus could be discerned, and frequently they were of a tremendous size, with numerous vacuoles in their cytoplasm and an eccentrically located nucleus. In some macrophags pigment was found even within the nucleus or only around the latter, showing the rest of the cell body filled with red blood cells.

The polyblasts also presented unusually well developed cytoplasm, round or irregular in shape, often cystic, and never homogeneous. Their nucleus was mostly pale, eccentrically located, irregular in shape, in the form of a horseshoe or biscuit. Some polyblasts contained more than one nucleus and unlike the macrophags showed no pigment or any other contents.

In addition to macrophags and polyblasts there were numerous other cells, namely, fibroblasts and gitter cells. The fibroblasts were frequently filled with pigment granules or small fat globules, and the gitter cells always showed in specimens stained with scarlet red an enormous amount of fat.

These four types of cells—macrophags, polyblasts, fibroblasts and gitter cells—were the principal elements scattered among the numerous capillaries and the meshes of the surrounding connective tissue. Elastic fibers were totally absent. The capillaries, especially the larger ones, were often thrombosed, always congested, but *never infiltrated*. Lymphocytes and polynuclear leucocytes were uncommon.

The explanation of the findings can be summed up as follows: A hemorrhage took place as evidenced by the presence of red cells scattered here and there, hemorrhagic foci, and pigment. An effort was made by various elements to clean up the membrane from the bloody contents. This is shown by the presence of macrophags and gitter cells filled with blood cells, pigment, and fat globules—the product of transformation of the red cells and probably of the fibrin. While the white cells, namely the polyblasts, are engaged in the building up of a new connective tissue, the red cells break up giving their pigment to the macrophags, their protein being transformed into fat by the gitter cells. In other words we find here a gradually formed new membrane exceedingly rich in vessels, but without signs of inflammation.

Horizontal or surface sections from the external pseudomembrane showed a marked cribriform appearance caused by numerous empty spaces that resembled lacunæ. The latter appeared mostly round, or oval in shape, were often tortuous, resembling the contours of vessels. They, as a rule, showed no contents, seldom were filled with red cells, some of which were sticking to their inner wall. Still more numerous were small vessels and capillaries, always distended, hyperemic, and covered with delicate fibers of fibrin. Connective-tissue fibers in the form of strands or bundles, were much more numerous than in the previous membrane, the fibers being separated from each other by red cells, polyblasts, fibroblasts, and macrophags. The latter two varieties of cells were packed with minute globules of pigment which, as in the previous membrane, were also freely scattered over the entire visual field. Some places showed none of these cells, but instead were covered with foci of hemorrhage. Elastic fibers, inflammatory changes, as perivascular infiltrations, and plasma cells, were here, as in the previous membrane, totally absent. In short, the pathological picture greatly resembled that of the previous pseudomembrane which was like the former in the process of organization. The examination of the dura itself gave a totally different picture. Horizontal or surface sections (frozen) from the inner layer of the dura showed first of all a great wealth of elastic fibers intermingled with fibers of connective tissue which usually were very thin, forming bundles separated from each other by small interspaces, some of which contained vessels or capillaries (Fig. 3).

In some places the fibers were separated from each other by oblong, rod-like, seldom oval nuclei, slightly granular in appearance and provided with a distinct membrane and nucleolus. Very infrequently the meshes formed by intersection of the connective-tissue fibers were filled with minute hemorrhagic foci, and small fibrin films. Capillaries and vessels were considerably fewer than in the pseudomembranes, and often showed a thickened adventitial layer. Pigment globules, macrophags, polyblasts, distinct hemorrhages as seen in the pseudomembranes were here totally lacking. The small hemorrhagic foci occasionally found here cannot be looked upon as pathological, being frequently met with in a normal dura (Nose[1]). The external layer of the dura studied with numerous stains showed no changes either, and appeared perfectly normal. On the contrary, the pia showed a wealth of pathological findings which can be gathered from the accompanying microphotograph (Fig. 4). This membrane is very much thickened, the meshes are greatly separated, widened, and filled with hemorrhages and numerous vessels. Some of the latter are thrombosed, some are much distended and hyperemic, some are *ruptured*, and the surrounding tissue is packed with macrophags, polyblasts, etc., and the blood penetrating into the adjacent arachnoid membrane. The same changes could be found in the brain tissue itself where the frontal, parietal, and temporal regions, and in part the occipital lobe, exhibited a great number of distended and hyperemic vessels. Yet, no inflammatory phenomena either in the pia-arachnoid, or in the brain tissue could be found. They were also absent, as I showed, in the pseudo-membranes.

Like the previous case, this one shows absence of any changes in the dura, but their presence, in abundance, in the pia-arachnoid. As in the previous case these changes cannot and must not be looked for in the dura and as in the previous case no signs of inflammation could be demonstrated anywhere. It is therefore unreasonable to speak of a pachymeningitis, which term implies an inflammatory condition of the dura.

The etiology in this case was somewhat complicated. The history of trauma may have something to do with the hemorrhage, but most probably the constitutional diseases—tuberculosis and syphilis found on post-mortem examination — combined with the head injury were responsible for the pathological findings. At any rate, the latter in hematoma of the dura and the subarachnoid cyst have, as I said, absolutely nothing to do with the dura, originating as they do in the pia, a suggestion made long ago by Huguenin.[12] Bevan Lewis,[13] Ford Robertson[14] and Middlemass.[15] This is also true for the third variety of pachymeningitis where the dura *appears* to be (but is not) enormously thickened, but this problem will be taken up in a separate contribution.

THE FOOT IN HEALTH AND DISEASE.*

By HENRY KELLER, M.D.,

NEW YORK.

LECTURER IN ORTHOPEDIC SURGERY, N. Y. POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; ATTENDING ORTHOPEDIC SURGEON, WEST SIDE GERMAN DISPENSARY AND HOSPITAL AND UNIVERSITY AND BELLEVUE COLLEGE CLINIC.

THIS paper is not intended to be a résumé of a subject that can easily be studied in any text book. My object in reading it is rather to call attention to certain conditions which are very frequently overlooked by the general practitioner, as well as by the orthopedic surgeon, and also to attempt to emphasize certain factors which may have an important bearing upon diagnosis, prognosis, and treatment.

In order to appreciate the subject it is well to understand what we mean by a normal foot. A foot is made up of a framework or skeleton, composed of twenty-six bones. Of these, nineteen are the so-called long bones, composed chiefly of hard, firm bony tissue, of smooth surfaces and various sizes, and joining with other bones at their ends only. They make up the five metatarsal and fourteen phalanges. The remaining seven bones of various sizes are composed of bone, loose and spongy in texture. They have the appearance of irregular pebbles and have many smooth facets forming surfaces for joining with adjacent bones by which each bone is in contact with from four to six others. These spongy bones form the basis of the foot, arch and heel, and together with the metatarsals form a dome-shaped foot, which we for convenience call transverse and longitudinal arches.

*Read before the Yorkville Medical Society, January 21, 1918.

The Arches of the Foot.—Robert Jones well pointed out that the foot as a base of support is a tripod resting on the heel, the head of the first metatarsal bone, and the heads of the fourth and fifth metatarsal bones. Each side of the triangle

FIG. 1.—Bones forming the arch of the foot, seen from the inner side; the astragalus is lifted up to show the bed in which it lies. (After Ellis.)

is arched. The outer side, formed by the os calcis, cuboid, and the fourth and fifth metatarsals, is so slightly arched that practically the whole length of it rests on the ground when standing.

The inner side of the triangle is strongly arched, the arch runs from the heel upward and forward to the neck of the astragalus, then downward, forward, and inward through the scaphoid, internal cuneiform, and first metatarsal bones, the ball of the great toe.

The third side of the triangle runs from the head of the first metatarsal bone to the heads of the fourth and fifth metatarsal bones and forms the first part of the transverse arch of the foot. This transverse arch extends backward throughout the whole of the fore part of the foot. The cuneiform bones and the cuboid bone are arranged in a transverse

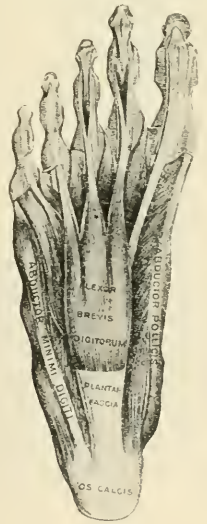

FIG. 2.—First layer of muscles of the plantar surface of the foot.

arch as well as the metatarsal bones.[1] The arches are supported by ligaments, muscles, and the plantar fascia, all of which help to keep the foot from spreading and help to support the body weight, and locomotion. (See Figs. 1 to 4.)

The Foot As a Passive Support.—"When the foot is actively used it is in great part supported by the muscles in addition to its ligaments and the strong plantar fascia, but when it serves as a passive support, as in standing, its normal elasticity allows the

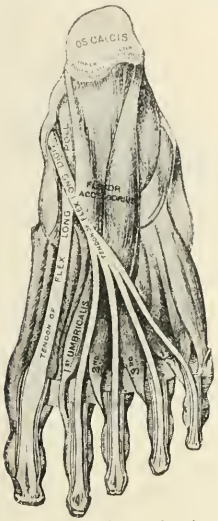

Fig. 3.—Second layer of muscles of the plantar surface of the foot.

bearing surface to expand as the arches are slightly depressed, the astragalus bearing the leg rotates inward and downward on the os calcis until it is checked by the resistance of the ligaments and by the interlocking of the bones. The head of the astragalus thus becomes slightly prominent, the inner border of the foot is depressed, and an attitude is attained in which the weight of the body is supported with the slightest muscular exertion. This is the attitude of rest. In order to enlarge the base of support for the body the feet turn outward during the passive attitude, and thus the muscles are relieved."

The Foot in Activity.—"In the function of locomotion the foot is a lever to raise and propel the body. The calf muscles supply the power, and the heads of the metatarsals serve as the fulcrum on which the weight is to be lifted. The foot must therefore be held in such relation to the leg that the line of weight, passing downward through the middle of the patella and ankle joint, is continued over the second toe, or practically the center of the foot."

The Normal Gait.—"The proper gait means that the feet are held parallel to one another, so that the line of the strain falls through the center of the foot. As one foot is advanced it first bears weight momentarily on the heel, then upon its outer border, the heel is then raised, and the body is lifted over the toes, the great toe giving the final impulse to the step, so that if the walker is looked at from behind he appears to be toeing in at the termination of each step. Hence during the walking the foot is under muscular control, and assumes the attitude most opposed to that of passive support."[2]

Abnormal Gait.—Whenever one assumes the persistent attitude of rest in walking, *i.e.* by turning one's toes out, abducting the feet, the strain falls upon the inner border of the foot, and in that way the normal functioning of his muscles of the foot is interfered with, and in due time the foot becomes a week foot.

Various Infections of the System and Their Effect Upon the Foot.—In my paper on diagnostic aids on diseases of bones and joints, after a thorough discussion of the various causative factors, I have concluded that "in order to make a proper diagnosis in diseases of bones and joints, it is necessary to ransack every accessible part of the body in order to locate the cause of the infection, tonsils, teeth, and gums, should be thoroughly inspected, the urine and feces should be analyzed carefully, and the organs of generation should be thoroughly examined. After we have germs which look suspicious, we should do our utmost to ascertain by scientific means whether or not this germ is the sole cause of the trouble or a contributing factor only."[3] Since the above was penned the brilliant work of Rosenow and Billings and others has proven conclusively how diligent one must be in finding the focus of lurking infection, no matter how insignificant or obscure, in order to be able to eradicate the bone and joint infection, coming on seemingly without cause.

Langroth, in his article on "Local Infection in Chronic Diseases,"[4] gives a summary of the cases treated in the clinic of the University of California Hospital, in which he shows that out of a series of eighty-six cases fifty-two were suffering from arthritis; of these 12 were acute or subacute, and

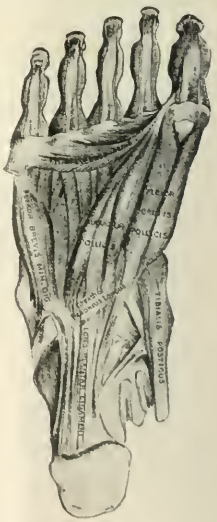

Fig. 4.—Third layer of muscles of the plantar surface of the foot.

66 per cent. of those had been associated with chronic focal infections, and responded well after removal of the foci even to the point of absolute cure, while 73 per cent. of chronic cases of arthritis were traced to a focal infection, and of those cases

able to be followed, many cases had less pain and no further progression of the disease after the removal of the focus.

The foot being composed of many joints, six synoviæ, and fourteen bursæ, and always exposed to

FIG. 5.—Shows the appearance of the tarsus in a child at age of 7 months; note the fulness and bulging of the soft parts surrounding the right ankle, caused by synovial effusion; compare this with the left side.

strains and exertions, one would expect it to be one of the first to bear the brunt of any systemic infection. Roland Hammond[5] in his study of infectious arthritis caused by nose and throat and accessory sinuses, reports a series of 61 cases, twelve of which showed positive nose and throat involvement after operation, and of these the ankles were involved five times and the feet without the ankles in one case. Eighteen cases had positive nose and throat evidence and were treated without an operation. Of those eighteen, thirteen had involvement of the ankles or feet or both.

In a series of 50 cases of gonorrheal arthritis that I had under my care in one clinic I found 30 had involvement of the ankles and most of them also involvement of the tarsal joints. Most of the feet were stiff and everted, and efforts had to be made to adduct and invert them, and in a good many it was impossible to do it without an anesthetic.

Benecke, quoted by Whitman,[2] has tabulated 78 cases of gonorrheal arthritis in 56 patients, of whom 18 were males, 38 females, with the ankle involvement in 9 and other joints of the foot in 6.

Influenza, typhoid, pneumonia, etc., may be the cause of foot infection.

Syphilis, in its later stages, supplies a good many cases of tarsal involvement. Pyorrhea, root abscesses of the teeth, and hypertrophied and suppurating tonsils, as the causative factor in arthritis, are every day occurrences in every clinic that deals with bones and joint diseases, a good many of these being involvements of the tarsal and ankle joints. Most of those patients will walk with their feet abducted in order to relieve the muscles from tension, just as one with an ordinary painful weak foot. There is, however, one important point of diagnostic significance which I wish to emphasize, namely, that whereas in ordinary painful weak foot the patient will be relieved of his pains after resting in bed for a while, and will not be disturbed in his sleep, the toxemic arthralgia will be aggravated toward morning, say at about 4 A. M. The reason for such aggravation may be the fact that, because of the sluggishness of circulation at night during sleep, the poison has no chance of being eliminated, and hence a greater accumulation, and aggravation of symptoms as a result. There is another important point which I wish to bring out in connection with the toxemic or infectious arthritis, and this remark is just as applicable to the ordinary painful weak foot, namely, that while the foot is painful and the arch tender, no metal supports should be applied. No dentist would ever dream of supplying bridge work to a patient when the latter's gums were inflamed. Rest, immobilization, or proper bandaging of the feet in adduction and inversion, with proper padding over the painful part, is the only feasible measure to take. Any other method is bound to aggravate the symptoms and prolong the suffering of the patient.

Circulatory Disturbances in Relation to the Foot.—In affections of the heart, such as myocarditis and stenotic diseases, we find that the sluggishness of the circulation will affect the lower extremities. The patient will feel cold in his feet, the toes will look bluish, and when pressure is made a white mark will remain for a while. Such disturbance may also be due to an abdominal tumor pressing

FIG. 6.—H. W. suffered from a painful ankle (left), diagnosed as sprain; *x*-ray revealed linear fracture of lower portion of fibula; note also the position of the os calcis in relation to the rest of the tarsus in a foot with normal arch.

upon the aorta or on one of the branches which supply either one or the other extremity. Because of the weakness of the muscles as a result of the sluggish circulation, the patient assumes a persistent attitude of rest while walking. Metal foot plates in

these cases will aggravate the condition, their pressure still further impeding the circulation of the plantar surface. One of the best aids in diagnosing this condition is the syphygmomanometer. The difference in the blood pressure between the upper and lower extremities in a healthy being is between 25 and 35. If, for instance, the upper systolic is 120 the lower is 145 to 155. The measurement in the lower extremity is taken at the bend of the knee posteriorly (about one inch lower) and to the outer side, at the exit of the anterior tibial. In myocarditis the blood pressure may be alike in the upper and lower extremities. Whenever there is some disturbance of circulation caused by pressure on one side there is disturbance of the above-mentioned ratio on that side only. In movable tumors of the abdomen causing pressure, there will be a differ-

FIG. 7.—Flat-foot and osteoarthritis of right tarsal joints; note abnormal relation of os calcis to the rest of the tarsus.

ence of the ratio depending upon the position the patients assume. In normal circulation the ratio of pulse pressure to systolic pressure in the lower extremities will equal that in the upper extremities, *i.e.* 3:1.

The Foot in Nervous Affections.—We all know that in various nervous affections the patient suffers from trophic disturbances which manifest themselves in a variety of ways, especially ulcerations of various parts, and the foot is one of the greatest sufferers. These, however, are fully described in text books, and we shall therefore pass them in silence. There is one important relationship existing between one known nervous disease and the feet, which although of great diagnostic importance, seems to have been overlooked by a good many writers, *i.e.* flat feet as one of the earliest signs of tabes dorsalis. Due to the loss of stability the patient unconsciously widens his legs—abducts his feet while walking; also on account of the loss of tonicity of the muscles of the feet the plantar muscles are relaxed, permitting a further spreading of the foot, with a yielding of the astragalus and a real flat foot as the result. The only difference being that whereas in flat feet, of such character, in an otherwise healthy being, it would be impossible to adduct the foot and invert it to the normal limit —18 degrees within a right angle to the leg—in tabetic patients, due to the hypotonicity of the muscles it is possible to invert it without any effort or pain to the patient. There are patients, however, who suffer from marked hyperesthesia of both lower extremities in early tabes.

One must always be on the lookout for such patients. A very prominent gastroenterologist referred a case of flat feet to me for treatment, and incidentally mentioned the fact that the patient had been under his care for two years, suffering from gastric catarrh. After thorough examination I found that the patient was suffering from tabes and that the gastric trouble was of a tabetic origin. The first thing that called my attention to it was the condition of his feet.

The Foot as an Indicator of a Joint Involvement.—"The heel is obviously intended by Nature, through both position and structure, to receive the shock of impact of the foot against the ground and support the greater part of the weight of the body and burden in standing, and at the beginning of a new step. The os calcis or heel bone is broad and strong, and articulates closely with the astragalus, which lies above and in front of it, and forms the keystone of the foot-arch. The rear prominence of the os calcis serves as the point of attachment of the tendo Achilles which lifts the heel and rear of the foot off the ground, and thus accomplishes the first movement in walking." (Munson.[6])

Whenever any joint of the spine or the lower extremity is diseased Nature tries to protect the diseased and painful joint from being jarred, by breaking the weight line and thus lessening the shock of impact. The patient will unconsciously flex his knee and walk on his toes, and avoid stepping on his heel. This is a very important sign. If after immobilization of the diseased joint the patient is able to step on his heels without pain, it indicates that the protection is complete, and we need no stilting as an additional protection, otherwise the patient must be kept off the limb if the trouble is in the lower extremity, and must be placed in a recumbent posture if the spine is involved.

X-Raying of a Foot.—Delitala[7] in his article on "The Normal and Pathological Anatomy of the Bony Framework of the Foot" shows that the most instructive exposures are the dorso plantar—the compressing tube parallel to the axis of the skeleton of the foot, and with the external margin of the foot lying on the sensitive plate—and the sole and compressing tube exactly perpendicular to the plate.

The rules that I laid down some years ago regarding the value of the *x*-ray in diseases of bones and joints will bear repetition.[8]

1. If the *x*-ray is negative and the clinical signs are positive, depend upon the clinical signs.

2. If the clinical signs are indefinite and the *x*-ray findings are definite, showing disease, bear the *x*-ray finding in mind, but make sure that the plate has been taken by an expert radiographer, that the part has received the proper exposure, and that the plate has been properly developed.

3. No surgeon should depend solely upon the radiologist for the interpretation of findings in the plate.

4. It is always advisable to take antero, posterior, an dlateral viefws in order to bring out all the features of the disease.

5. In order to recognize an injury or a disease around a joint, especially in young individuals, it is necessary to remember the time of development and ossification of the epiphyses. (Fig. 5.)

6. The plaster-of-Paris is permeable to the rays, while zinc oxide plaster usually mars the clearness of the shadow, and should never be applied to the part to be *x*-rayed.

7. The normal as well as the diseased or injured side should be taken for comparison. The slightest deviation from the normal can in that way be detected. In order, however, that such comparison should be of value it is necessary that both be taken in the same position and at the same angles.

8. In reading the *x*-ray plate it is necessary to read the soft parts as well as the osseous shadows, for the former may sometimes prove to be of greater importance. (Fig. 5.)

9. In painful feet without any particular cause do not fail to *x*-ray the teeth for a possible cause.

Method of Determining Degree of Flatness of the Arches.—The footprint method of determining the degree of flatfoot is misleading and should be discarded. Because a person has a flat plantar surface does not mean that he is in need of treatment. The plantar muscles may be so developed by constant exercise that they actually fill up and obscure the entire plantar arch contour. Such a foot, in spite of its flatness, is in perfect working order and should not be interfered with. Obese people may also have a flat plantar surface due to a thick fatty pad obscuring the normal outline.

On the other hand, a patient who has a high instep may suffer intensely from arch strain although the footprint will be perfect. It is therefore not the flatness of the arches but the attitude of the foot while walking that counts.

The Psychological Significance of Injuries and Diseases of Lower Extremities, Including the Foot.—Inanimate objects have certain inflexible physical laws by which they are governed, and the application of those laws is all that is necessary to get the same results. In dealing with human beings we must take into account the human and psychic element, and every individual is a law unto himself in that respect. Whenever a man has sustained an injury which will necessarily confine him to his home for a longer or shorter time the following facts must be faced: (1) He is deprived of his normal mode of living. (2) His suffering will impress itself upon his mind, and after the actual pains have ceased there will linger the impression of those pains in the subconsciousness which will tend to perpetuate the helplessness of the patient. It is therefore self-evident that the sooner the patient is restored to his normal environment the less chance there is for him to become obsessed with his helpless feeling.

The injuries of the lower extremities are therefore of more concern to the conscientious physician on account of the necessity of keeping the patient's weight off the injured limb, and hence the indoor confinement, with its accompanying dangers, enumerated above, must perforce be prolonged. If the patient should attempt to bear weight on the injured limb before it is restored to normal every step will enhance the suffering, and in that way induce a condition of "algophobia," even after the original cause has disappeared.

The following therapeutic measures in dealing with injuries of the lower extremities are therefore obvious:

1. Early and proper immobilization of the injured limb, in order to eliminate the pain due to motion. Plaster-of-Paris bandages, properly applied, seem to serve that purpose best.

2. The encouragement of the patient to leave the bed as soon as practicable and have him walk with the aid of crutches.

3. Removal of permanent support should be postponed until after the patient has been trained to walk without crutches and has regained his self-confidence. This prolonged immobilization has the effect of making the patient forget his previous incapacity and pain, and the early regaining of his sense of security usually results in the ability of the patient to support himself on the injured limb without any difficulty soon after the permanent removal of his immobilizing bandages.

4. In short, the necessity of bearing the old truism in mind that in dealing with ailments and injuries affecting human beings we are dealing with beings in possession of emotions, impressions, and a nervous system in control of the impaired machine, and not, as a good many seem to think, a simple, lifeless apparatus in need of repair.

Eugenics in Brazil.—There is a Eugenic Society in the enterprising city of Sao Paulo, the first to be organized in that country. The object is frankly to improve the race and render it worthy of so grand a country. The subjects to be covered in this connection are the laws of heredity, the propagation of knowledge of eugenics and hygiene and the spread of education in general. This plan of instruction aims to inform the public as to the harm wrought by syphilis, alcoholism, tuberculosis, etc. Other activities are regulation of prostitution, prenuptial examination, and all steps which will diminish the birth rate of degenerates, idiots, etc. It is to be hoped that this patriotic movement will be taken up by other Brazilian states.—*Brazil-Medico.*

AN UNDEVELOPED OPPORTUNITY FOR THE STUDY OF THE PROGNOSIS OF CHRONIC DISEASES.

By W. C. RAPPLEYE, M.D.,

FOXBORO, MASS.

PATHOLOGIST, FOXBORO STATE HOSPITAL.

THE most important and vital features of medical knowledge is a proper understanding of prognosis of diseases. The internist may make a brilliant diagnosis, the electrocardiographer may reveal previously but little understood anomalies of heart behavior, the laboratory worker may render an unexpected and significant opinion, the pathologist may make exhaustive analyses of post-mortem findings, all of which represent exceedingly important sources of information and give to present-day students of medicine opportunities for diagnosis not afforded to their predecessors of but a few years. And yet these varied accomplishments and armamentaria of increased efficiency fail to take into consideration the most vital feature of disease from the viewpoint of the patient and the progress of medical therapy, namely, prognosis.

The patient himself is interested in a brilliant diagnosis or the discovery of a formerly overlooked unique feature of his ailment only in so far as it concerns his future health and his life. He is interested in the diagnosis itself primarily only in so far as it throws light upon the possibilities of his future, and he is more interested in knowing to what the present findings point than in what the disease may be. It is the outcome rather than the diagnosis which interests the patient.

That a physician may understand the prognostic import of the conditions he finds and of the diagnosis which he attaches to the presenting clinical pictures implies a knowledge of the life history of the disease in question. This is particularly true in the chronic diseases which are becoming yearly of more importance and an increasing cause of mortality. With the knowledge of the entire course of a given disease, the development of abnormal signs or the progression of present signs carries a definite significance to a man so trained and forms the basis of an intelligent prognosis.

Such a training implies not only a knowledge of abnormal signs and their significance, but quite as well the normal variations which may carry no prognostic or even diagnostic import beyond that they may be recognized as deviations from the normal. This matter is well illustrated in the examinations of recruits and the return of men in active service to base hospitals, in both of which groups are found very considerable numbers of men possessing a supposedly valvular heart disease because of the presence of murmurs. The great frequency of blowing systolic murmurs or whiffs at the base or apex of the heart is a matter of general observation, but they are too frequently ascribed an importance to which they are not entitled. Another illustration is in the promptness with which a diagnosis of nephritis is made upon albumin being discovered in the urine or an elevated blood pressure found at examination. It is true, of course, that these features require investigation, but should be recognized only in their relation to the whole clinical picture.

The only method whereby the significance of various signs and symptoms in a given disease can be properly determined is by studying the disease from start to finish. One should see the disease at its very earlist manifestations, or, better still, study the individual before the disease has appeared. It should be followed step by step throughout its course and every sign, symptom or treatment recorded, and this method applied to a number of cases so one may secure a grasp of the variations and responses in a number of patients afflicted with the disease.

Since the problem of prognosis in chronic diseases is one of securing adequate study of these diseases from the very onset, it is well to inquire into the present methods of making such study. It is at once evident that the opportunities offered for the study of chronic diseases, from their very onset to termination, are indeed few, and this very paucity probably explains the incomplete knowledge we possess of their prognosis.

Our thoughts turn to the wards and laboratories of general hospitals where chronic diseases are studied and investigated, and where annually many patients suffering from them are treated. But it is apparent that the opportunities which these students and investigators have are not as great as one might expect, for they see but a cross section of the disease, and gain but little idea of its onset and evolution, and the short time the patient is kept in the hospital adds only fragmentary information.

It is true that after discharge from the house patients are followed in the out-patient departments, and further knowledge is acquired during the months or years that such patients are followed. But the records of these cases are inadequate, the difficulties of following cases are very great, and the infrequency of examination of the patient tends to discount the actual value of the efforts as a study of prognosis. The establishment of out-patient classes for diabetes, nephritis, tuberculosis, and other diseases is designed in large part for treatment, though valuable information relating to prognosis is gathered. The follow-up work of social service organizations is also contributing toward the sum total of our knowledge of diseases, but here again the possibilities are greatly restricted.

The frequent appearance in out-patient clinics of individuals showing early evidence of disease allows some study of the early progress of the process. But merely because the process is not well established and the actual evidence of disease is slight, these patients are not sent into the house for study, where more accurate and valuable data could be collected. On the other hand, the cases usually sent into the house are in stages when the signs are well established and treatment directed largely to palliative methods. Could the patients showing obscure indications be more thoroughly studied under the facilities found in the hospital wards, much valuable information could be obtained, and our knowledge of the early evidences of a disease process be greatly enhanced.

Granting that the present method of inquiry is inadequate in forming comprehensive understanding of the development and course of chronic diseases, it is well to ask as to other possibilities.

It must be borne in mind that only a small, though ever-increasing proportion of the sick enter hospitals or are cared for in the out-patient departments, the greater number seeking advice and treatment of the practitioner. To the practitioner, then, is offered an unusual opportunity for the very sort of study to which we must look for further contribution to our understanding of prognosis. It is he who sees the cases early in their development, who is called at the appearance of symptoms, and who has an opportunity to follow the disease throughout its course. A general realization of these opportunities, however, is wanting, for but little in the line of study and research is done by the general practitioner, though the remarkable contributions of Sir James MacKenzie to our knowledge of affections of the heart is a striking example of what can be done by a practitioner.

While the practitioner has the opportunity to see the process of disease as it is not seen in hospital practice, the ability to utilize such opportunities is limited. As a rule, the practitioner has not the equipment to carry on the accurate studies which should be made on patients under observation, and the remuneration for doing so would be out of proportion to the benefit evident to the patient. The majority of practitioners have not the time to do this kind of work, granted that they may have the necessary laboratory and other equipment. And to provide technical assistants who can do the work entails an expense which most practitioners feel unwilling or unable to assume themselves. And though endowments and funds are available for similar work in established institutions, it is to be deplored that no provision is made for study of the courses of diseases where they can better be observed.

We look also to life insurance statistics for information relative to the potential significance of various evidences of disease, but our hope is futile. One obtains but little knowledge of the prognostic value of signs and symptoms of disease from these records, and the infrequency of examinations of policyholders to ascertain new features makes the value of the records but slight.

The possibilities in community medicine, contract medicine, and various organizations designed to build up better health and longer lives, are as yet imperfectly developed, though from them we should gain some information.

The opportunities offered by State institutions for the study of prognosis in disease are little recognized, and developed less, and yet these hospitals offer provision for a better study of the problem than any other means. It is here that the patients are under observation for years in many instances, and, unlike the patients under the care of practitioners, they are seen regularly, at any time, and as frequently as desired. The development of laboratory and other facilities for accurate study of these patients in State hospitals insures that sufficiently comprehensive examinations can be made so that the value of various manifestations of disease may be appraised with accuracy. New developments in disease can be recognized early, and their prognostic import, or possible relations to other features of the disease, determined. The considerable proportion of patients dying in State hospitals upon whom post-mortem studies are done allows for further corroboration of diagnosis and study of the disease upon which considerable data had been collected during life. By such a correlation of clinico-pathological data, with supplementary study of the necropsy findings, the recognition of a not inconsiderable and unimportant group of relationships could be expected. The value of such a study, if sufficiently comprehensive, is obvious.

That the opportunity for studying the prognosis of diseases with which internal medicine is primarily concerned does carry some promise seems apparent. For example, in the State of Massachusetts a very considerable proportion of the cases of pellagra reported to the State Board of Health is found in the State institutions. Here such patients are living under an environment and on a diet along with many other individuals, most of whom do not suffer from nor later develop the disease. The large number of controls, the ease with which dietary changes can be made, and the facility with which frequent observations can be made, are evident, and the likelihood of knowing the ultimate outcome is great. And it is somewhat this very sort of study to which pellagra has been subjected by numerous investigators.

The early enthusiasm of workers in neurosyphilis, which allowed them to predict by the goldsol test the seat of the syphilitic process, whether of the parenchyma, vessels and meninges, or interstitial tissue and other localizations, to which predictions could be attached prognostic importance, has been replaced by a more conservative attitude. For the subsequent development of these same cases has not borne out the earlier predictions in their entirety, and as the number of carefully and completely studied cases increases, our valuation of this particular test in delineating the principal seat of the process becomes adjusted.

The prognosis of various diseases of the kidneys and the signs or symptoms developing during the course of such diseases is still a matter of much uncertainty because of our incomplete knowledge of the course of chronic interstitial nephritis, for instance. This particular problem has been of special interest to us, and a start on the study of the disease, humble in its proportions, to be sure, has been begun, having in mind to gain early recognition of the disease and to follow it through in as many instances as possible. Since 70 per cent. of the patients dying here are studied postmorten, it is to be hoped that some value may be attached to the ante-mortem study. The studies have thus far been confined largely to blood nitrogen, chloride and sugar determinations, urine and blood-pressure examinations, the determination of phenolsulphonephthalein excretion, etc., in their interrelations and their possible relationship to the structural changes found on later study of the kidneys themselves. Only a small beginning has been made, but the attempt has yielded some encouragement, at least. The various chronic diseases of liver, heart, pancreas, endocrine glands, neuromuscular system, and other organs, require much study, the scope of possibilities is great, and the intensive study of them over long periods is sure to yield results.

The importance of focal infections in chronic diseases is being much emphasized, and the literature pertaining thereto is rapidly becoming voluminous. The frequent relief of troublesome symptoms and

the more favorable progress of treatment, in many instances, upon the removal of a septic focus, need no emphasis. The exact mechanism of such improvement is not always clear, and careful clinico-pathological studies in greater numbers should give us further understanding of the great importance of focal infection. The recent development of dental hygiene, the training courses for dental hygienists, and the utilization of these individuals in our State institutions, permit us to study this very important feature, the role of suppurative oral foci in chronic diseases, under well-controlled conditions.

That the spirit of such studies can be misconstrued seems unlikely. An increasing appreciation of our duties to the patients in State hospitals requires that we devote our best efforts toward their proper care and treatment. That we should understand their condition and the diseases from which they suffer is requisite to that intelligent care and treatment. The insignificant discomfort to which they might be subject by examination is only the experience of every patient in general hospitals at large. On the whole, the cooperation of the patients is very good, almost as good as it is with people in general.

The greater development of pathological and clinico-pathological laboratories, the introduction of the new methods of blood analysis, and various other features of diagnosis and investigation, and an awakening responsibility to the patients themselves, stimulate us in an endeavor to study the diseases which are found so commonly among the patients, and in so doing further our knowledge of the diseases themselves. It is by availing ourselves of this as yet but little developed opportunity of studying disease where we have both facilities and the patients under prolonged and constant observation, where we have an opportunity to follow diseases throughout their entire life history, that we may hope to obtain more complete and reliable information relating to prognosis than by the other less satisfactory methods.

A NEW TEST OF HEART FUNCTION.

By ALBERT ABRAMS, A.M., M.D., LL.D.,

SAN FRANCISCO CAL.

THE writer believes that, in his "Diagnostic Therapeutics,"[1] the first systematic attempt was made to execute the diagnosis of visceral insufficiency. From the work in question the following citation is excerpted: "While the scientific diagnostician strives to make the clinical correspond with the anatomic findings, or, in other words, pictures to his mind the pathologic conditions prevailing in disease, the less radical physician is often content, and reasonably so, with a functional diagnosis. The latter takes cognizance of anomalies in the physiologic functions of the viscera. Thus a functional takes precedence over a pathologic diagnosis, for the reason that physiologic fluctuations may be resident in an organ even before a pathologico-anatomic substractum is assumed to exist." It was Wunderlich who declared that, "Pathology is the physiology of the sick."

At one time in the evolution of cardiopathology, the dominant fetish of the cardiologist was the anatomic lesion and functional capacity of the heart was practically disregarded. The condition of the cardiac muscle and the recognition of its frontier signs of insufficiency constitutes the new prevailing viewpoint of the clinician.

Various tests have been suggested to determine the functional integrity of the heart and they may be grouped as follows:[2] (1) Reaction of the heart muscle to active and passive exertion; (2) Behavior of the heart to reflex stimulation (reflexes of Abrams and Livierato); (3) Estimation of sodium chloride elimination; (4) Use of clinical and instrumental methods. The use of these methods predicates skill and the possession of intricate and expensive apparatus.

The following practical method based on the "cardiosplanchnic phenomenon of Abrams" is at the ready command of any physician.

Cardiosplanchnic Phenomenon.—Many cases of cardiac insufficiency, according to Sir James Barr,[3] owe their symptoms to a gravitation of blood into the abdominal cavity and "these phenomena have been aptly termed cardiosplanchnic paresis by Albert Abrams." The phenomenon[4] in question refers to the increased area of dullness of the right ventricle when pressure upon the abdomen squeezes the blood from the splanchnic veins into the right heart.

In the norm, the quantity of blood thus expressed from the abdomen is small, but in cardiac insufficiency it is increased. A normal cardiac muscle is able to cope with this sudden augmented influx of blood as expressed by an increase of blood pressure, while the contrary effect ensues with enfeebled cardiac musculature.

Technique.—The sphygmomanometer is applied in the conventional way.* After estimating the systolic pressure, maintain the mercurial column at a point showing the least oscillations. The latter maneuver is best attained by a stopcock on the rubber tube leading from the source of air supply. Next, direct the patient to compress the abdomen forcibly as in the act of defecation.

When the integrity of the heart muscle is not compromised the blood pressure will rise from 1 to 40 mm. of mercury, or it will sink from 1 to 20 mm. in the converse condition. The rise or fall will be in direct ratio to the condition of the cardiac muscle. It is evident that several factors will influence the degree of the rise and fall, notably the pressure exerted by the ventral musculature. Despite this fact, however, this simple and rapid test has yielded the writer the most efficient practical service.

*The writer invariably estimates blood pressure with the patient facing the geographical west. He has found that such pressure will vary (however slight) according to whether the patient faces east, north, south, or west. The visceral tone of the heart, as he has shown elsewhere, is influenced by cosmic energy and every living being is a transformer of energy.

2135 SACRAMENTO STREET.

Military Medicine.

The Physiology of the Aviator.—It is patent that to be successful in flying the machine must be good and the aviator himself must be physically and mentally well qualified for the work. The successful flier is in many respects a man apart, that is, he possesses certain inborn traits that peculiarly mark him out as an aviator. There is in fact the aviator type of man. The problem of selecting men for the flying corps at the present time is extremely difficult. It seems that upon the flying corps the issue of the war very largely depends. The nation or army which has the largest number of efficient aviators will win the war. Therefore every effort is being made to train pilots and observers as quickly as possible. This being so, as Dr. J. C. McWalter points out in the *Medical Press*, August 21, 1918, officers in charge of training squadrons have no time to waste on pupils who are slow to learn, who are lacking in enterprise, who are unlucky with their machines, or who seem to exhibit any lack of keenness for their work. Learners of this stamp are forthwith rejected as unlikely to develop into efficient airmen.

While in existing circumstances, this is perhaps, inevitable, McWalters says that those who, like himself, have served as medical officers to the flying corps, know that many of these men, rejected as inefficient, are really the victims of various physical ailments, as diseases of the ear, nose, throat, spinal cord, or heart, or are the subjects of transient trouble such as hay fever, coryza, or influenza. Moreover, it must be taken into consideration that the physical qualifications of a flying officer become higher every day. Men are now required as a matter of course to fly at 15,000 to 20,000 feet or more, and putting on one side the troubles due to extreme cold or to atmospheric rarefaction at great heights, which may be overcome by artificial means, a person has to possess a remarkably elastic vascular mechanism before he can descend with impunity and in a few minutes, from a height of 20,000 feet. Not only must the cardiac muscle be in a healthy state and the heart generally be in a robust condition, but the lungs and bronchial membranes must be sound and must also be proof against the irritation engendered by the heat and smoke of the engine or by the varying moisture of the air. In short, a man to be passed medically for the flying corps must be in the first instance young and must be in addition strong constitutionally and fit and sound in every respect. A man may have all these absolutely essential qualifications and yet not be competent as a flier. Defects existing in the nervous system or in the ear and nose, less often the eyes or throat, are sufficient to disqualify.

According to McWalter the most usual and, at the same time, the most dangerous defect, is some disease of the labyrinth. In examination this defect is often overlooked, being unlikely in its milder forms, to cause any acute trouble until the patient has mounted some thousands of feet, when it then gives rise not only to vertigo and dizziness, but to a lack of that sense of equilibration and location which is the very essence of the successful flying man. Also it has been found that those aviators who experience most difficulty in judging of the distance from the ground when approaching a landing place, are frequently the subjects of this defect. In the opinion of McWalter the entire series of rhinological ailments, stenosis, sinusitis, hypertrophy of the turbinated bones, Eustachian tube troubles, even pharyngitis and tonsillitis, all render in a greater or lesser degree a man unfit to fly.

It is then obscure defects and those which in other circumstances might be regarded as minor defects which constitute, perhaps, the chief disabilities of the would-be flying man. As long as flying was done at relatively low heights these defects were of not much account, but now that a good deal of the flying is done at 15,000 or 20,000 feet their significance is grave.

The French authorities have a method whereby they submit the aviator neophyte to a series of nerve shocks to test the integrity and stability of his nervous system. However, it is asserted that this system fails in its object to a large extent, because the phlegmatic individual of good physique and of excellent constitution may pass with ease and yet be found wanting. He lacks the higher qualities of initiative, enterprise, resource, ingenuity, and readiness which go to make the ideal aeronaut and which the frail, highly strung man of delicate nervous organization often does possess. In proof of this it may be said that some of the best fliers have been men of this type. Prompt reflexes, intact cerebellar sense, perfect sense of projection, are among the most important tests for an aviator. All catarrhs, especially nasal and bronchial, are constant sources of danger. Even a tendency to wax in the ears seems to produce a dangerous giddiness and vertigo. The pulmonary apparatus must be in first class condition, and the tests to prove this must be severe. The color tests should also be stringent, as it is through this sense that judgment as to the exact distance of the ground when about to land, is rendered accurate. Correct judgment in this respect involves an intact color sense because the various greens and browns of the landing place are often refracted through a bluish mist which obscures the true distance. Finally McWalters states that an accurate sense of projection in space, such as is elicited when a candidate can touch with closed eyes an object which he has once seen, is one of the surest tests of a man for aviation.

Examination of candidates for the aviation corps places now greater responsibility upon the medical man than does any other form of military examination. It requires on the part of the medical examiner a thorough conception of the problem from the point of view of the physiology, psychology, and pathology of the aviator. It must be borne in mind that comparatively little is known regarding the medical aspects of aviation. The literature is scanty and experts are naturally few. However, some salient points stand out. The candidate must be young and physically and constitutionally sound. Especially must the ear apparatus of the flying man be

practically perfect. Therefore it is incumbent on the medical examiner to look carefully for such defects. Likewise the whole series of rhinological disorders must be eyed askance in examining an aeronautical candidate. The tests should be in every instance severe and searching, as the fate of liberty may depend on the efficiency of the flying man.

Pulmonary Tuberculosis in the Military Service.—Professor Stahelin recently delivered an address on this subject before the Basle Medical Society (*Correspondenz-Blatt für Schweizer Aerzte*, June 1). The first case shown was a man of the landwehr who on January 28, 1918, had to take up his military duties. He was 37 years old and had been employed in an institution. For the first two weeks all went well, then he seemed suddenly to lose desire for food. He felt a heaviness after eatitng and his bowels did not act. He waked depressed, with backache. On February 26 he reported ill. The stomach contents after trial breakfast were almost neutral, no free HCl. After a time he rallied and took on weight. He had doubtless passed through an acute gastritis. The author, bearing in mind that the latter often masks tuberculosis, had the patient x-rayed and the shadow showed evidences of old febroid phthisis. The alternative diagnosis was pneumonoconiosis and this was excluded by a positive tuberculin reaction, râles appearing over the right apex. There was a history of attacks of acute influenza every winter since 1905. The case, therefore, typical of chronic febroid phthisis of the benign type with good prognosis. In every case of gastric failure we must investigate for tuberculosis. The next case was of an electrician aged 21, who was seized with vomiting while in military service. As a little blood was present the diagnosis was ulcer. He was evacuated to a sanitarium for treatment, where he complained of severe epigastric pain and pressure pain. With marked loss of weight and subfebrile temperature the case suggested tuberculosis, but looked more like pernicious anemia. The man was sent to the author's clinic, where his blood and stomach contents were found normal. The only find was enteroptosis. The tuberculin reaction was negative. A stomach support relieved all his symptoms; the x-ray showed in a beautiful manner how the support held up the stomach. Such a result is not common. The patient was discharged in December, about three months after his first days of illness. The following May he was back with a different picture—cough, fatigue, chilliness, and night sweats. There were râles over both apices and a remittent fever. The progress of the affection was rapid and tuberculosis appeared in the larynx and intestine. Death resulted within the first year of the disease.

This case showed that the gastric symptom was a prodrome or mask of incipient tubercle. The subfebrile temperature at that period tended to show that the disease was already present, but in a stage in which diagnosis was impossible as shown by the negative tuberculin test. Had the latter been repeated in a larger dose, however, the results might have been different. In another case after 1 mg. of tuberculin had given a negative result 2 mgs. caused a local reaction in the lung and unmasked a tuberculosis which had appeared as a laryngobronchitis with slight friction sound on the left side. Such cases are common, but we are still ignorant as to the connection between these dry pleurisies and tuberculosis; the latter may set in soon afterward or not for a long time or not at all. The author has followed up fourteen military cases of dry pleurisy for several years. In 4 recovery took place, 2 were in doubt, and 8 had not recovered. The four recovered cases might develop the disease in time. During the same period there were also 14 cases of exudative pleurisy, of which 6 had recovered, 3 were in doubt, 4 had not recovered and one was dead. Of the 28 pleurisy patients 10 returned to military service. The author is not sure that this course is wise, certainly the regiment surgeon should keep an eye on such soldiers. From the standpoint of military insurance it would be a heavy load if the third or so of recovered pleuritics who had returned to duty should develop tuberculosis.

Morbidity in a Military Hospital for Neuroses.—A neurological center in a certain Italian army comprises a so-called Neurocomio for functional maladies of the nervous system, a division of a general hospital for organic nervous affections, and similar provisions for deaf mutes and insane. The first named is described by Tamburini and Fabrizi in the *Giornale Italiano di Medicina Militare* for July 31. It was originated in 1916 and went into effect at the beginning of the following year. Its scope comprised reeducation as well as the cure of neuropathics. The term "functionally mutilated" was employed to distinguish these unfortunates from structurally mutilated soldiers. The capacity of the neurocomio was 60 beds, of which 4 were for officers, and there were also 20 beds for military auxiliaries. During the first 18 months the number of patients treated was 427, of whom 21 were officers. During the first twelve months 101 men were discharged cured and 95 improved, while only 30 were unimproved. The largest contingent were the hypotonics, numbering nearly a hundred. About as many were the victims of hysterical deafness and deaf mutism. Ten had the diagnosis of simple hysteria, 21 of neurasthenia, and 5 of psychasthenia. Other types of hysteria represented were hysterical stammering with 19, hemiparesis 14, blepharospasm 2, amaurosis 3. There were 9 cases of myoclonus or similar clonic spasms or tremor and 7 of astasia-abasia. Five were diagnosed as cyclothymia. There were a few cases of organic affections, despite the restricted character of the material, which were doubtless postorganic and quasi-functional in character.

Few Drug Addicts Among Drafted Men.—The greatly exaggerated reports as to the number of drafted men rejected because of drug addiction have led the War Department to publish the actual figures. Of 990,592 men examined in the draft up to January 1, 1918, only 403 were rejected for drug addiction and only 76 discharged for this reason. The ratio of rejections in the draft for drug addiction is only one man in each 2,500.

Red Cross Calls for More Hospitals.—Mr. Harvey D. Gibson, now managing the National American Red Cross in France, has cabled to the Ameriman Women's Hospitals for six more hospitals to care for the American sick and wounded in France. Two hospital units are needed immediately. Each of these units should have ten women physicians, ten nurses's aids, and the hospital equipment and tentage of the standard United States Army 100-bed camp hospital, with a truck, camionette, touring car, and chauffeur. The American Women's Hospitals already have three hospitals in France, which are conducted under arrangements with the French Service de Santé.

Home for Red Cross Nurses Opened.—With more than 1,000 Red Cross nurses always quartered in New York on their way to or from the front the need of a homelike place where they may find rest and recreation has been felt for some time. This has been met by a new nurse home which was opened with appropriate exercises at 11 West Tenth Street, on October 10.

Deaths in the Service.—Major Clarence Fahnstock of New York died of pneumonia in France on October 9, aged 43 years. He was a graduate of New York University Medical College, in 1900, and chief surgeon of the 301st Infantry of the Camp Devens Division before going to France. He was a member of the New York Academy of Medicine and well known as a big game hunter, having made trips to the African wilds and to Alaska.

Lieut. Karl E. Schmid, M. C., U. S. Navy, of San Jose, Cal., died at the Pelham Bay Naval Hospital, on October 9.

Capt. Warren T. Walker, M. C., U. S. Army, of Syracuse, N. Y., lost his life during a fire in the officers' quarters of the United States Army Base Hospital No. 3, Colonia, N. J., on October 10.

Lieut. Austin Latting Hobbs, M. C., U. S. Army, of East Orange, N. J., died of pneumonia at Meuil la Tour, France, on September 26, aged 34 years.

Army Tuberculosis Bill Well Supported.—The indications are that Congress will take a favorable view of the recommendations of the public health officials that a chain of great hospitals or sanatoriums be established in this country for the treatment and care of discharged soldiers and sailors who are suffering from tuberculosis. The Clark bill, now before the House Public Buildings Committee, calls for $10,500,000 for the establishment of a chain of fourteen sanatoriums. The bill provides for the expenditure of most of this sum in enlarging existing hospitals.

Chicago Museum Becomes Hospital.—The Field Museum of Natural History in Grant Park, Chicago, which is nearing completion, and has cost $7,000,000, has been turned over to the Government for use as a hospital. The interior will be rearranged so that 4,300 patients can be accommodated and a number of smaller buildings will be erected around the main structure for the accommodation of 1,000 nurses. The museum building covers six acres and has more than twenty-five acres floor space.

No Abatement of Influenza in the Army Camps.—The number of new cases of influenza reported from the army camps for the week ending October 11 have been averaging over 12,000 daily. The total number of influenza cases at the camps on the above date since the beginning of the epidemic has reached 223,000; pneumonia cases 27,000, and deaths 8,333.

Red Cross Work in England.—The latest instalment of the report of the American Red Cross deals with work and expenditures in behalf of American fighting men passing through England. Expenditures in this work from October, 1917, to June 30, 1918, including contributions to the British Red Cross and British Ambulance Committee, total $4,313,568. For the work in the United Kingdom for the last half of this year an appropriation of $4,483,800 has been made. Work is well advanced on three new Red Cross Hospitals in England. One of these is near completion and has been opened. It is for naval men and is located in London. One is at Sarisbury, near Southampton. This will be the largest military hospital in Great Britain when completed and will be equipped to care for 3,000 wounded. A second military hospital is located at Windsor Great Park.

New Naval Hospital in Brooklyn.—A four-story, reinforced concrete building is being constructed on Flushing Avenue, near Emerson Street, Brooklyn, which is to be used as a naval hospital. The building has a floor space of 280 by 200 feet and is to have six wings. The contract calls for the completion of the building within 129 days. Accommodation will be afforded for 1,200 patients and 250 nurses. The estimated cost of the hospital is $950,000.

Philadelphia Home for Naval Hospital.—Mrs. Arthur Brock has given the use of her residence on Spruce Street, Philadelphia, for use as an emergency fleet hospital.

Major-General William C. Gorgas, recently retired for age, has been reinstated on the active list and assigned to the same rank of the Medical Corps. It is announced that he will complete his inspection of medical facilities in France and will then return to the United States to report. It is rumored that his next appointment may take him to Italy.

Lieutenant Robert O. Blood of the Medical Corps of the 103rd Infantry has received the Distinguished Service Cross for extraordinary heroism in action near Bouresches, France, on July 20-23, 1918, where he worked constantly in the most exposed positions, establishing a dressing station in an advanced position that was continually under shell fire.

Proposed Reconstruction Hospitals in New York.—North Brother Island is to be the site of a huge reconstruction hospital for the War Department, if the recommendation of the joint commission, which has recently been sitting in Washington, is adopted. The hospital would have from two to three thousand beds. The commission also recommends the acquisition of the newly completed Westchester Infirmary, at White Plains, which would have, under the commission's plans, between 1,000 and 2,000 beds.

BRONCHOPNEUMONIA COMPLICATING SCARLET FEVER.

THE diagnosis of bronchopneumonia occurring as a complication in scarlet fever is, *per se*, in the majority of cases, easy, but, as has been pointed out by Hutinel, there are in the state of the nose, throat, ears, and lymph nodes, sometimes even in that of the joints, heart, or kidneys, so many reasons for explaining the high temperature and the serious manifestations of the disease, that not infrequently an examination of the lungs is overlooked. However, the physician's attention should be on the alert, given the high temperature, the dyspnea, and occasionally the cough; but although the functional signs are constant and manifest, the same cannot be said of the stethoscopic evidence. The disseminated, deep-seated small foci cannot be detected by percussion, while the numerous loud râles of bronchitis may conceal the fine, scarce, subcrepitant râles deep in the midst of the pulmonary parenchyma.

The differential diagnosis from lobar pneumonia complicating scarlet fever is likewise delicate. If the case is one of pneumonia-scarlet fever, the commencement is that of a general infection with chills, fever, vomiting, and diarrhea, with dyspnea and occasionally cough, soon followed by the characteristic signs of pneumonia. If the case assumes the torpid type described by Teissier, the striking fact is the absence of functional symptoms, with subdullness at one base with some crepitant râles fine in character, with or without a pneumonic souffle. Finally, during convalescence a sudden rise in temperature, with a painful spot in the thorax, will usually indicate the commencement of a focus of pneumonia. A pleural empyema at its beginning may assume certain clinical aspects of bronchopneumonia, and it must not be forgotten that it may follow a bronchopneumonia; but whether primary or secondary, the diagnosis is not always an easy matter.

Once the diagnosis of bronchopneumonia has been made, the question immediately comes up as to whether the process is tuberculous or not. The problem is difficult to solve; but in favor of tuberculosis are the great thermic oscillations, the presence of only fine subcrepitant râles and souffle, and, above all, perhaps, the long evolution and personal antecedents of the little patient.

The prognosis of bronchopneumonia of scarlet fever is serious, and the mortality may be placed at between 60 and 75 per cent. The factors of this prognosis are the malignancy of the scarlet fever, the presence of an ulceronecrotic angina, purulent rhinitis, and suppurating otitis. The younger the subject the more frequent will be the lethal complications. The prognosis is still more unfavorable when a purulent pleurisy is present, for the operation for empyema, even when resorted to early in the process, is successful in less than 50 per cent. of the cases.

As to treatment, the scarlet fever must be attended to in the first place, but, as in the bronchopneumonia of measles, the cold pack and tepid baths of eight to ten minutes are indicated. Hutinel is a warm advocate of adrenalin in the malignant forms of scarlet fever. It raises the arterial tension, but its exhibition should be continued until convalescence is assured, after which the dose is progressively decreased.

SYPHILIS AND CANCER.

IT has been asserted that a relationship exists between syphilis and cancer, the former being said to prepare the way for cancer, to render the soil favorable to neoplastic invasion. Dr. Casalis de Pury, writing in the *Paris Medical*, some time ago, concerning syphilis and cancer among the Basutos, upholds this view. The author is qualified by experience to write with authority regarding the Basutos. His grandfather, who was a contemporary of Livingstone, was the first missionary among them, and was followed twenty-five years later by his father, a medical missionary, and after a similar interval by himself. The history of this African tribe during the period in which these French missionaries worked in their midst is interesting, and bears closely on the subject matter of this article. In the time of the grandfather of Dr. Pury, the tribe practised communism, and flourished; prostitution was regarded as a deadly sin, was severely punished, and almost unknown. When the diamond mines of Kimberley were opened the Basutos flocked to them, and brought back syphilis to their own country, a malady up to that time unknown among them. The disease is stated to have produced extensive lesions of the bones and ulceration, with rapid cachexia, but chronic syphilis affecting connective tissue was not observed. When Pury himself arrived communism had passed away and given place to European particularism. Civilization had also brought its special vices and diseases; prostitution was common, and syphilis was general, the stigmata of hereditary syphilis being seen on every side. Cancer also had not been observed up to then. Pury was informed by his father that although he had been on the lookout for it for twenty-five years he had never seen a case. However, after this time cases

began to crop up—carcinoma of the liver, breast, uterus, and cervical glands, and osteosarcoma, all attacking young subjects and especially syphilitics. Epithelioma, common enough among the Boers, had never been observed among the Basutos, and the author recognizes the relation of cause and effect between the syphilis affecting bones and glands and the cancer of the same tissues, both in young subjects and in a soil previously free from neoplasms.

At the Cape, Pury found cancer very frequent among the Dutch, not so frequent among the Anglo-Saxons, but rife among the Dutch-Hottentot halfbreeds, who were also the most syphilitic. On visiting the Basutos after the Boer war, he found syphilis diminishing in intensity, but cancer becoming more and more prevalent. It attacked persons between 30 and 40. Cancer of the tongue and lip, despite much smoking, was to all intents and purposes unknown. From his experience in Africa the author is of the opinion that syphilis prepares the ground for cancer, and says that he holds the view that there is an incontestable hereditary syphilitic cancerous diathesis.

Statistics should be of great service in assisting to throw further light on this matter. If it can be shown that cancer is more prevalent where syphilis is common an *a priori* argument will be supplied in support of the theory that syphilis prepares the soil for cancer. It has been noted before that cancer comes with civilization and with the increased prosperity of a people. Whether the determining factor in such cases is syphilis, or increased consumption of meat, or constipation due to changed habits of living, or even other disturbances of metabolism, is yet to be ascertained.

INSANITY IN PERU.

Delgado and Bambaren, internes in the Lima Insane Asylum, contribute a statistical paper on insanity to the *Anales de la Facultad de Medicina* for January-February. The institution contains all the insane in Peru who require custodial care. The number of inmates in 1916 was 522, a notable increase over 1906, when the number was 377. During the period 1896-1906 the increase was much less. The augmentation for the past decade was due almost entirely to increase in the number of female insane, who from 172 in 1896 and 170 in 1906 increased to 267 in 1916. The increase in males was marked for the 20-year period but not for the decade just expired. It appears as if the increase first showed itself in males, and a decade later in females. The general increase in twenty years is not peculiar to Peru, for the same behavior is noted in most other countries. The causes for such increase have been freely discussed by alienists of note—Maudsley, for example.

A survey of the forms of insanity which obtain in Peru yield some surprises. Paranoia tops the list with 22.6 per cent. This can hardly be the paranoia of Kraepelin, but probably includes all insanities with paranoid symptoms. That most of these cases must conform to Kraepelin's paranoid dementia appears from the very low percentage (4.02) with the diagnosis of dementia precox. One is impressed with the great infrequency of general paresis, which is represented by only four cases—less than 1 per cent.

Next in frequency to paranoia is psychosis of degeneracy with 12.06 per cent. Mania comes next with 9.38, epilepsy 7.85, alcoholic insanity 7.85, and melancholia 6.13. There are in the institution 21 idiots and 3 imbeciles. The authors attempt an etiological classification, which falls short because in nearly a third no one causal factor can be assigned. The leading factor specifically mentioned is organic disease, and next in order come moral, toxic, and hereditary causes, in the order named. No attempt is made to analyze the material under each grouping, but it is only too apparent that two or more of these factors could readily be discovered in the average patient.

The authors make no attempt to explain the increase of male insanity for 1896-1906, nor that of female insanity for 1906-1916. One hardly feels like criticising this omission, for it is obvious that in a decade the viewpoint undergoes such changes that the diagnoses of one epoch are not those of the successive one. The remarkably small number of imbeciles in Peru can only be explained by the universal tendency to keep weak-minded women debiles shielded at home. We recall that in one of the minor novels of the late Henry James the young Peruvian lady whom the American immigrant weds was clearly of this type. The amount of alcoholic insanity seems large for a Latin race, but this form shows no increase, and the authors neglect to state whether Europeans are represented. The authors neglect to state also whether the increase of insanity was absolute or relative, as they give no ratios of incidence to population.

HOW MUCH RISK SHOULD BE TAKEN IN ADVISING PATIENTS?

The public sometimes inveigh against the "play safe" advice of the physician, and claim that he is always endeavoring to save his status at their expense. Like the man who was seeking a lawyer who would tell him what he could do, instead of what he must not do, they sometimes wish a medical adviser to give them counsel which in the abstract would be adjudged foolhardy, yet which meets the situation in a special case. No one can read anecdotal history and biography without realizing that a vast amount of theoretically bad advice has been given with the best results by the leaders of the profession when confronted with peculiar exigencies of practice, and especially when clients of great importance to the community are concerned. No doubt can exist as to the fact that the leader of the profession shows his qualities of leadership in no more striking way than when he is forced to substitute for conservative advice some recommendation which makes him liable to suffer in reputation should fate go against him. But the sole question is not that the advice may react against

the physician, for the moral element is sure to enter into the hazard in many of these cases.

Let us give a concrete example of a case without moral hazard: A gentleman who was slated for a most important administrative position in a great corporation chanced to be suffering at the time from a protracted neurasthenia consecutive to a severe attack of influenza. On account of the strain which this position would entail he was advised to refuse it until at least a year had elapsed. The most expert as well as the most disinterested advice was concurrent on this point. However, he took some advice (which he clearly wanted) from two comparatively humble friends, one a physician and the other a psychologist. It was argued by these men that opportunity would never knock at this man's door again, at least so strongly. It was also argued that if he allowed himself that year's leeway he would surely overvalue the material factor in his case and look upon himself as a potential neurasthenic who might break down at the first stress of his new position. He took this advice, and in assuming his duties at once he assumed them as an invalid who could work only on part time. It was severe for him at first, but he adjusted himself to his duties, which in time proved to be a veritable occupation cure for his nervousness. This was over twenty years ago, and the patient has never had a breakdown during that period.

Interrelation of the Ovaries and the Thyroid.

In an article dealing with the results of radium therapy in hyperthyroidism (*International Journal of Surgery*, July, 1918), Dr. W. H. B. Aikins notes that in several of the cases so treated it was stated that exophthalmic goiter followed the removal of the ovaries. This naturally gives rise to speculation, he says, with respect to the relationship which exists between the organs of internal secretion. Aikins deals with this subject at some length, and draws attention to the fact that statistics show that exophthalmic and other forms of goiter are more frequent in women, thus suggesting a connection between the thyroid and gonad secretions. That there is such a relationship, he says, appears to be proved by other physiological facts, and also accepted by many. The practical deductions that Aikins draws from the assumption that the relationship between the ovaries and the rest of the ductless glands is intimate, is that it would be advisable to take the correlation into consideration before deciding to perform double oophorectomy, seeing that it is not only the effect of the operation upon the genital system that must be considered, but the effect also upon the other ductless glands. If the functions of one of the endocrine organs are injured or interrupted a severe strain is put upon the others, the machinery of the body is thrown out of gear, and serious pathological results may ensue. A smooth and harmonious working of all the internal secretions is essential to the maintenance of good health, and therefore the relationship between the ovaries and other ductless glands should always be taken into account when dealing with abnormal gynecological conditions.

Movement of Epidemics in 1918.

From the bulletin of epidemiology of the *Office International d'Hygiène Publique* for July it appears that cholera has prevailed extensively during the first half of the present year in but one country, the Province of Bengal, in which nearly 20,000 deaths occurred during the three first months of the year. The number of cases in the Philippines up to April 20 was nearly 2,000, and about 1,400 of these cases were fatal. The disease is known to exist in European Russia, but no data are obtainable. No country contiguous to Russia is mentioned, the nearest being Syria. Here also statistics are wanting. The reportable area comprises southern and southeastern Asia and the outlying islands. The bubonic plague occurred only sporadically in northern Africa, Peru, and Brazil. In Senegal, however, about 1,500 cases have occurred, with a mortality of 1,200. In Guayaquil alone 154 cases have occurred, with 97 deaths. In Asia the disease has occurred sporadically in China, the Dutch East Indies, Indo-China, Siam, the Straits Settlements, Arabia, and Ceylon, and the great toll, as usual, is in British India, with 611,337 cases for the first six months of the year and 493,074 fatalities. The provinces to suffer most were the United Provinces, Bombay and Sind. Punjab and Rajputana. Yellow fever had an off year; cases occurred in Brazil, Ecuador, Guatemala, Honduras, and Mexico, but the aggregate was very slight.

News of the Week.

The Influenza Pandemic.—The reports of the past week show that the influenza continues to spread throughout the world, having reached even to South Africa. According to medical testimony the worst plague that ever visited that quarter of the globe was nothing in comparison with the present epidemic. There have been as many as 20,000 cases of influenza in the hospitals of the mining district of Natal. Some of the mines have been closed and the local railroad service is curtailed. An increasing number of cases of influenza are being reported from all sections of the United States and according to a statement made by the Public Health Service a still further increase is to be expected, since 30 to 40 per cent. of the population are usually affected by the disease. Reliable detailed reports as to the extent of the epidemic in various localities are not available as yet. From September 18 to October 11 25,082 cases were reported in New York City, with 394 cases of pneumonia, 183 deaths from influenza, and 210 deaths from pneumonia. The most serious phase of the situation in New York City is the shortage of nurses. To meet this a Nurses' Emergency Council has been formed, and through this organization the Red Cross is making a house to house canvass for women with any knowledge of nursing. The various medical colleges of the city have released their fourth year medical men who are acting as nurses under the direction of graduate nurses and physicians. The Board of Estimate has appropriated $55.000 for the use of the Health Department in combating the epidemic, and the Health Commissioner has taken the un-

usual method of asking the political district leaders to use their party machinery to hunt up influenza cases. Instructions have been sent out from the headquarters of the Red Cross in Washington to all Red Cross chapters in reference to mobilization in an effort to combat the influenza epidemic. The Red Cross will work in cooperation with the Public Health Service and the State Boards of Health. It will enroll nurses for the campaign and will use freely its accumulated hospital supplies. Surgeon General Blue has suggested that all places of amusement be closed and all public meetings be discontinued in all places where the malady has become prevalent.

STATEMENT OF THE PUBLIC HEALTH COMMITTEE OF THE ACADEMY OF MEDICINE.

The Public Health Committee of the New York Academy of Medicine, after conferring with representatives of the Health Department, hospital authorities, bacteriologists, and others in close touch with the situation regarding influenza, are of the opinion that, while there is no occasion for undue alarm on the part of the public, further vigorous measures should be taken by the Department of Health to prevent the spread of the disease, and, in collaboration with every available public and private agency, to ameliorate the condition of patients and of their dependents.

In the communities in which the disease has thus far appeared in epidemic form the rate of sickness has been high and the death rate not inconsiderable. In this city the unusually heavy demands upon private physicians, hospitals, dispensaries, and district nursing organizations indicate of themselves the presence of an epidemic which should be vigorously combated. Many individual physicians in general practice report seeing from thirty to fifty cases a day, and declare that they are so busy as to be unable to make prompt reports of influenza cases to the Department of Health. The pressure upon certain hospitals for the admission of influenza cases has been so great as to necessitate the temporary conversion of wards ordinarily used for surgical and other purposes to emergency wards for influenza and its sequelæ. A number of the municipal hospitals have been overcrowded, either by placing mattresses on the floor or, in the case of one hospital, by placing two or even three children in one bed. Some physicians and district nurses engaged in work among the poor report that in numerous instances, upon visiting patients to whom they have been called, they have learned of other cases in the same houses which were unattended and necessarily unreported. Reports are by no means exceptional of whole families which have come down with the disease; where this has happened among the poor there has been not only a lack of medical care, but suffering from loss of income and lack of food. A block census made on October 9 of a typical upper East Side tenement block showed that among 340 families, numbering 1,445 persons, there were 160 cases diagnosed by physicians as influenza, of which only nine had had hospital treatment. This means that in this block, up to October 9, 11 per cent. of the population has been affected. If anything approximating this rate holds for the entire city, Greater New York has already had several hundred thousand cases of influenza; and the epidemic is apparently still on the increase.

Further evidence of widespread illness among the population has been obtained by inquiries variously directed. In a group of offices in one of the largest buildings in the financial district more than a third of the office force was reported to be absent on account of illness on October 9. Isolated factories in the Borough of Manhattan report from 12 to 20 per cent. of illness. The disease is prevalent today in all or nearly all of the military and naval centers in and around New York.

Returns from a group of more than fifteen large public hospitals show that from 12 to 40 per cent. of the medical and lay workers in such institutions have been affected during the past two weeks. One hospital in Brooklyn reports 56 nurses down with influenza or pneumonia out of a staff of 120. Another in Manhattan reports 50 cases out of 300; another 40 out of 200. These reports are similar to reports received from the military hospitals. In one cantonment hospital 100 out of 200 nurses have been ill. There is no reason for supposing that the epidemic will run a different course in New York City from that which it has pursued elsewhere.

The disease is of germ origin and probably is spread most commonly through germ-laden droplets of mucus thrown into the air in unguarded coughing, sneezing, and spitting. The Public Health Committee therefore strongly endorses the educational propaganda which has been carried on by the Health Department of New York City and other health authorities throughout the country, warning the public against the dangers of overcrowding and lack of sunlight and ventilation, as well as those arising from ignorance or careless habits.

Experience both abroad and in this country seems to indicate that the epidemic runs its course in any given community in from four to six weeks. Occurring at this season, the epidemic in New York City will probably begin to decline in from two to four weeks. During this period the situation will continue to be critical and should be dealt with as effectively as possible.

The following measures are recommended:

1. That the public should be sharply warned of the danger of close contact with unrecognized cases of influenza in crowded public places.

2. The community should stand squarely behind the Department of Health in its efforts to minimize overcrowding in public conveyances by conscientiously observing the prescribed hours for the opening and closing of various classes of mercantile establishments.

3. The daily inspection of children on their arrival at school, as practised by the Department of Health, represents a principle which should find wider application. There should be a daily inspection of workers employed in all large establishments as they report for work, with a view to the prompt exclusion and, so far as possible, the segregation of all suspects.

4. During the epidemic employers should voluntarily report all employees who are absent on account of illness. Such reports will help the Department of Health to locate many neglected cases.

5. Gauze masks should be used by all physicians, nurses, and others in attendance upon or in close contact with the patients suffering from influenza.

6. Measures should be taken to secure more complete and uniform reports of cases of influenza. The cooperation of physicians will be the readier if it is made clear that the reports are desired as a basis for helpful action.

7. Nurses, social service workers, and others having cognizance of neglected cases should report them, and centers at which such reports can be readily made in person should be established.

8. The city authorities should strengthen their forces by arranging promptly for the close cooperation and, if necessary, the financial support of the United States Public Health Service, the Department of Civilian Relief of the American Red Cross, and of all agencies which are able to offer useful service in the emergency. A specific task should be assigned to each cooperating agency and its subdivisions.

9. Every report of a case, especially in the poorer districts, should be made the basis of action either by the Department of Health or by a cooperating agency, with the following objects in view:

a. Removal to hospital where necessary and possible.

b. Medical care at home. In the block canvass referred to above it was ascertained that while a majority of the patients had been seen by a physician once, few had had subsequent medical attention.

c. Nursing care at home. The nursing program should include the use not only of graduate nurses, but of all women who have had sufficient nursing experience to be of service.

d. The provision of food for the needy cases and for the neglected children of sick mothers.

e. Temporary shelter for children whose mothers are sick at home.

f. Inquiry into conditions among the close neigh-

bors of stricken families, with a view to the prompt recognition of unreported cases.

10. Hospitals should be urged to obey the injunction of the Department of Health to discontinue all non-urgent medical and surgical work in order to afford partial segregation and medical and nursing care for influenza and pneumonia patients.

11. The overcrowding of hospital wards with cases of influenza and pneumonia should be discouraged. Where hospitals command sufficient personnel to care for larger numbers of patients than under normal conditions, such patients should not be crowded into existing wards, but should be placed in adjacent spaces, such as day rooms and corridors. It is essential to hospitals caring for influenza patient to maintain a proper system of bed spacing and screening.

12. Owners of apartment and tenement houses should provide heat for such buildings during morning and evening hours. The proper ventilation of apartments may thus be secured without undue exposure to cold. The prevalent idea that the Fuel Administration has forbidden the heating of apartment houses before November 1 is erroneous. The committee is advised by the Fuel Administration that reasonable discretion is all that is desired or expected.

Unidentified Epidemic in Argentina.—The National Medical Department of Argentina is alarmed over the spread of an unidentified epidemic among the children of the Province of Catamarca. In the course of a month 100 children have died out of a population of 10,000. The disease resembles dysentery and is highly contagious. All vessels from France, Portugal, Spain, and Italy are now carefully quarantined.

Cholera Spreads in Berlin.—According to a despatch from Basel, cholera is spreading in Berlin despite rigorous preventive measures. Seventeen cases were reported on October 8 and fifteen deaths are reported to have occurred from the disease on this date.

The Fourth National Exposition of Chemical Industries, which was held in the Grand Central Palace, New York, during the last week in September, was a success far beyond the most sanguine expectations of those interested in its promotion. Practically every branch of chemistry and allied lines was represented. It was particularly significant in that it demonstrated that America has within a few years freed itself from the domination of German Chemistry and showed what has been accomplished by this country in taking the enormous chemical, glass, and dye industries away from Germany. Particularly during the last year have great strides been made in the industries based on chemistry and in synthetic medicinal preparations. The Fifth National Exposition of Chemical Industries will be held at the Coliseum in Chicago during the week of September 22, 1919.

New Maternity Center for New York.—A new branch of the Maternity Center Association was opened on October 11, at 412 West Forty-seventh Street, in Health Zone No. 5, between Twenty-sixth and 105th Streets. In this zone there have been reported in one year 7,643 births and 931 deaths of infants under one year of age.

Dr. Walter B. Swift of Boston has been appointed consultation expert for speech defects to the Division of Medical Inspection of the Public Schools of Cleveland, Ohio.

Dr. Frederick Tilney, professor of neurology, delivered the address before the College of Physicians and Surgeons at the opening exercises of Columbia University on September 25.

Clinical Congress Abandoned.—Dr. Franklin Martin, Secretary-General, announces that the Clinical Congress of the American College of Surgeons will not meet in New York during the week of October 20. Because of the epidemic of influenza this action was taken with the approval of Dr. Charles H. Mayo, the president, and the authorities of the Army, Navy, and Public Health Service.

Public Health Meeting Postponed.—Owing to the prevalence of influenza in all parts of the United States, the executive committee of the American Public Health Association postponed the annual meeting of the association which was to have been held in Chicago during the week of October 14.

The Harvey Society.—The first lecture of the series will be delivered at the N. Y. Academy of Medicine on Saturday evening, October 19, 1918, at 8.30, by Dr. E. K. Dunham. Subject: "Certain Aspects of the Application of Antiseptics in Military Practice."

Gifts to Columbia University.—Gifts totalling nearly $37,000 were announced at the meeting of the trustees of Columbia University on October 7. They included $9,000 from the trustees of the East River Homes Foundation to be applied toward the work in tuberculosis at the medical school and $5,000 from an anonymous donor to be used in surgical research. Contributions of $1,000 each were made to the fund to provide for the admission of women to the medical school by William H. Moore, Arthur Curtiss James, Elizabeth Waterbury, Forrest F. Dryden, J. M. Wallace, D. G. Reif, and F. L. Hine.

Heavy Fines for Spitters.—The New York City Health Department, in its effort to combat the spread of influenza, is carrying on an energetic campaign against spitters. At one of the police courts fifteen men were fined $20 each for spitting on subway platforms. In other courts the fines ranged from $1 to $5. One magistrate announces his intention of handing out a sentence of five days in the workhouse without an option of a fine.

Obituary Notes.—Dr. WALTER WILLIAM LOWELL, a graduate of Cornell Medical College in 1911, and a member of the New York State and Kings County Medical Societies, died of pneumonia at his home in Brooklyn, on October 10, aged 28 years.

Dr. JOHN RICHARD PERKINS, a graduate of the College of Physicians and Surgeons of Columbia University in 1915, and an interne in the Presbyterian Hospital, New York, died of pneumonia in that institution on October 9, aged 26 years.

Dr. JACOB CHASAN, a graduate of the Long Island College Hospital in 1911, died of pneumonia at his home in the Bronx on October 9.

Dr. HERMAN GROSS died at his home in Metuchen, N. J., on October 6, aged 38 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1903, and head of the Metuchen Board of Health.

Dr. CLINTON E. STARK died of heart disease at his home in Norwich, Conn., on September 26, aged 62 years. He was a graduate of the New York

Homeopathic Medical College, in 1878, a member of the American Institute of Homeopathy, and a former president of the Connecticut State Homeopathic Society. Dr. Stark was largely instrumental in securing the establishment of the Norwich State Hospital.

Dr. FRANK T. MARA of Boston, a graduate of the Harvard University Medical School in 1887, died at St. Elizabeth's Hospital of pneumonia on October 3, aged 52 years.

Dr. JOHN GEORGE FREDERICK HOLSTON of Zanesville, Ohio, a graduate of Jefferson Medical College, Philadelphia, Pa., in 1867, died at his home on September 26, after a prolonged illness, at the age of 73 years. He had recently celebrated his fiftieth anniversary as a practitioner of medicine.

Dr. OMAR BADGER of Skowhegan, Me., a recent graduate of Harvard University Medical School, and first assistant physician in the Boston City Hospital, died of pneumonia in that institution on September 25.

Dr. JOHN W. PARKHILL of Colliers, W. Va., a graduate of the American Medical College of St. Louis in 1876, died in a hospital in Steubensville, Ohio, from injuries sustained in a railroad accident on September 25, aged 65 years.

Dr. G. ROY HEATON, a graduate of the Atlanta School of Medicine in 1911, died at his home in Rockmart about September 22, aged 31 years.

Dr. THOMAS WOLFF, a Confederate veteran, and for some years a practitioner of medicine in Washington, D. C., died following a stroke of apoplexy, on September 26, aged 74 years.

Dr. A. A. FIELDING, a practitioner of medicine of Knoxville, Tenn., died September 26, at an advanced age.

Dr. ALBERT CARL RICE died of pneumonia at his home in Babylon, L. I., on October 11, aged 32 years. He was a graduate of the University and Bellevue Hospital Medical College in 1910, and visiting surgeon to the South Side Hospital, Babylon.

Correspondence.

INSUFFLATION OF OXYGEN IN PNEUMONIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—About a year ago I published an article (*Jour. A. M. A.*, October 6, 1917, pp. 1150-56) on "The Therapeutic Value of Oral Rhythmic Insufflation of Oxygen," in which I gave the description of a simple apparatus for its execution. I am old and experienced enough to know that at best it takes a long time before such publications reach the minds of practitioners and are the means of practical application. The present epidemic, however, induces me to ask you for space to call attention to my previous statements and to urge the use of oxygen by this method in respiratory and cardiac diseases. The administration of oxygen in respiratory disease is certainly not new. There is hardly a physician who will permit a patient to die without having recourse to the administration of oxygen. On the other hand, there is hardly a physician who is not skeptical of the value of its use. There are two reasons for this attitude. In the first place, physicians were influenced by the opinion of physiologists that the air has sufficient oxygen for the need of the body and that the hemoglobin cannot take up any more of the oxygen even when administered under high pressures. Furthermore, physicians have actually not seen any favorable effect from the administration of oxygen. As to the first reason, physiologists and clinicians failed, and still fail, to see that a distinction must be made between the effects on physiological and that on pathological conditions. The great surpluses of tissue and functional activities possessed by the normal body are factors of safety to be used just in pathological conditions. Recently, however, some physiologists and clinicians changed their views regarding the value of oxygen in disease. Haldane, an authority on the respiratory gases, and who belonged to the group of physiologists who were more than skeptical as to the value of oxygen inhalation by normal persons (athletes, for instance), came out strongly in favor of administration of oxygen in inflammatory conditions of the lungs. The following statement deserves to be quoted. He says, for instance:

> It may be argued that such measures as the administration of oxygen are at the best only palliative and of no use, since they do not remove the cause of the pathological conditions. As a physiologist, I cannot for a moment agree with this reasoning. The living body is no machine, but constantly tending to maintain or to revert to the normal, and the respite afforded by such measures as the temporary administration of oxygen is not wasted, but utilized for recuperation.

As to the second reason it is probably an actual fact that practitioners rarely see any favorable effect from the administration of oxygen. The reason for this failure, however, is due in the first place to the faulty method of administration. It is usually given through a paper or glass funnel kept at some distance from the patient. By this method the inspired air is hardly enriched with oxygen. Another vicious factor is the lateness of the period of the disease when oxygen is begun to be administered; it is done in the terminal stage. This part of the procedure is so well known to the lay public that a conscious patient who receives oxygen will ask whether he is so desperately ill that he needs oxygen. In the above mentioned article I described a simple apparatus for the administration of oxygen and by testing it on normal individuals it was found that after a short period of administration by this method the tracheal air consisted practically of pure oxygen. I cannot repeat here the description of the apparatus; I must refer the reader to the above mentioned article (and also to my article in the MEDICAL RECORD for July 7, 1917). The essential parts of the apparatus consist in a flat hollow, tongue depressor-like tube and a "respiratory valve" by means of which inspiration and expiration are accomplished. The apparatus is, of course, not patented and consequently comparatively inexpensive.* The flat tube should be inserted into the mouth to about the middle of the tongue. It gives no inconvenience to the patient who should be asked to keep his lips closed over the instrument.

There has been at least one instance of a patient in a dying state from pneumonia (Type II) whose life undoubtedly was saved by the administration

*George Tieman & Co., 107 Park Row, New York City, are the makers of it.

of oxygen. It relieves the agonies from air hunger and it most favorably affects the cyanosis, sometimes in less than one minute. The treatment should begin at an early period; it should be administered every two or three hours for five to ten minutes at a time. Care should be taken that at the start the oxygen insufflation should begin with low pressure; a sudden blast will frighten the patient who may refuse to take it again. The following little details are not superfluous. The ring of the respiratory valve which is moved by the inserted thumb should move easily. The waste of force leads to a premature fatigue of the thumb and also to the breaking off or to a dislodging of the ring.

A well known clinician obtained this instrument soon after my description of it. Several months later he was taken ill with a fatal pneumonia. It was the patient's wish that the apparatus should be used on him. A friend from the Rockefeller Institute who went over to assist in caring for the patient found that the ring of the respiratory valve was broken off and the apparatus altogether in disorder. It is simple common sense that an apparatus, if it should serve its purpose, should be handled with proper care and be often overhauled before there is an emergency for its use. The metal hollow "tongue depressor" should of course be pulled out from the rubber tubing after being used and should be disinfected.

The present epidemic form of pneumonia is characterized by an early appearance of cyanosis. Oxygen administration should therefore be begun very early. It is a matter of common sense that it will not help in 100 per cent. of the cases. But there is no remedy which helps 100 per cent. and the patient should receive the benefit of the doubt even if the rendered assistance may not exceed the value of 5 per cent. Physicians must free themselves from the idea that treatment is only of value when it can make a claim to specificity.

S. J. Meltzer, M. D.

Rockefeller Institute.

THE VALUE OF SODIUM BICARBONATE FOR COMMON COLDS.

To the Editor of the Medical Record:

Sir:—Having just experienced again personally the remarkable power of bicarbonate of soda in arresting a "common cold" I cannot refrain from mentioning it for the benefit of those who are not familiar with its value, about which I wrote long ago.

For a day or two I felt the "cold" coming on, and yesterday it was about at its height, with repeated sneezings, some coughing, and the use of many handkerchiefs. Last evening it was almost unbearable as I sat writing, when I bethought myself of soda, which I had given to scores of patients for many years. At 10.30 I took about half a teaspoonful in one-third of a tumbler of water, and repeated it each half hour to 12 o'clock—four doses. It had not then given much relief, and I went to bed with a handkerchief, though hardly expecting great trouble. I dropped to sleep almost at once, and slept perfectly till called at 7.30, and awoke minus the cold. By about 10 I felt a slight return and began the soda, taking three or four doses, which cleared all up, and the handkerchief has been a superfluity to-day.

My usual directions are to take four doses at half-hour intervals and a fifth one hour after the last. Then to wait about the same length of time and repeat the dosage if it seems necessary, and even a third series of doses if the cold is not checked, which is very rarely the case. Often the first series of doses is quite sufficient. Since I first suggested this treatment some years ago, many physicians have corroborated its value, speaking or writing to me about it.

When there is a grip element I have for many years given ten grains of phenacetin with twenty of soda, every two hours, with hot water, with equally remarkable results, as very many patients will testify. If heart depression is feared, a trifle of whiskey may be taken in the hot water, but I rarely find this necessary. In past years I have taken these powders myself very many times, and given them to my office associates and family, with invariably good results, and rarely, if ever, do we have any prolonged illness.

With the modern skepticism as to the value of drugs in general, it is encouraging to know something positive which has borne the test of long experience. L. Duncan Bulkley, M.D.

531 Madison Avenue, New York.

INFLUENZA PRECAUTIONS.

To the Editor of the Medical Record:

Sir:—The best combination as a protective and curative remedy against influenza is the following:

℞ Ammonii salicylatis.....grs. lxxii
Caffeine .....gr. vi
Essence of pepsin.....5i
Aquam ad.....5vi
Sig.: A dessertspoonful every hour.

The perforated zinc inhaler is the best protective mask. A little oil of eucalyptus, pine-needle oil, or preferably creosote, alcohol, and spirit of chloroform, equal parts, poured on the sponge of the inhaler, and breathed quietly, will prevent contagion being carried from a sufferer to a well person, even through unprotected sneezing or coughing.

Beverley Robinson, M.D.

OUR LONDON LETTER.

(From Our Own Correspondent.)

VICISSITUDES OF THE MINISTRY OF HEALTH—THE DANGER OF DRUG INFLUENCE—RABIES IN ENGLAND —SHUTTLE-KISSING.

London, Sept. 19, 1918.

Until now it has been believed that some sort of general agreement existed between the Friendly Societies—that being the generic title for all the organizations whereby the working classes club together to obtain medical benefits—and the official committees of the National Insurance Commission as to the provisions of the bill which promises to erect in the immediate future a ministry of health. It has now been definitely stated by chairmen of insurance committees that however far such an agreement may have existed in the more preliminary stages, the bill in the present form of its draft is quite unacceptable to the Friendly Societies of the country. A ministry of health erected on provisions that recognized all the claims of the Friendly

Societies would certainly be quite antagonistic to medical views, and so far as the medical profession is concerned the fact that the Friendly Societies do not like the bill as it stands is far from proving that the measure is other than a perfectly good one. But none the less it is very important, when legislation of such scope as the creation of a first-class state department is in question that the preliminary debates in the House of Commons should take place in an atmosphere of general agreement among the important parties concerned. A bill which begins its career in a welter of dissension in respect to basic principles does not often get on the statute book in any useful form. The bill should be a short one, protracted debates should be avoided, and the whole subject of a ministry of health should be regarded by legislators an urgent war measure; as a method, in short, by which the country can be enabled to deal in a comprehensive and safe manner with the burdens which will be laid on the health of the nation by the colossal war. The Friendly Societies come into the picture as the representatives of large groups of persons who are entitled in return for payments made by themselves to medical benefits under the act, and the policy of the Friendly Societies, some of which are wealthy bodies with considerable powers of political organization, is to secure as far as possible the conduct of the machinery by which medical benefits are administered. There has long been a feeling among medical men that the aims of Friendly Societies are dictated rather by official desire for influence than by particularly acute sympathy with the pathological conditions of their subscribers. Medical men, therefore, remain unmoved at the information that alterations have been made in the draft measure which make it distasteful to the Friendly Societies, except that opposition to the bill, stage-managed by the Friendly Societies, might contrive to delay the introduction of a much-needed measure, or at any rate prolong the early stages of legislation.

At the Central Criminal Court a nurse has recently been found guilty of murdering an infant placed under her care at the Welfare Center, Lower Sydenham. This center is a well-managed institution, and has received grants both from the Local Government Board and from the Borough Council of Lewisham, and the nurse in question was employed at the institution upon written references from a woman who personally knew her and was acquainted with the character of her work. The knowledge of this referee, seems, however, to have been very partial. The nurse was engaged at the end of May and was almost immediately put on night duty, remaining for the next ten days alone in discharge of her work from 8 o'clock in the evening until 7.30 the next morning. During that period three of the children under her care developed symptoms of meningitis, and in the case of the particular infant who died the post mortem examination revealed fracture of the skull. The nurse was suspended from duty when the proper investigation of her antecedents revealed that for ten years she had been a drug taker, unbalanced in her mental attitude, subject to fits, and even suicidal on occasion. The only defense possible was made, namely, that the injuries to the particular infant whose death was the origin of the indictment for murder were caused by the prisoner in a moment of mental irresponsibility, and upon that defense to the charge of murder the jury found the nurse insane, and Mr. Justice Darling directed that she should be detained as a criminal lunatic. Two morals can be drawn from a story of particular horror. One is so obvious that it requires no emphasis in a medical paper, namely, that the position to which persons addicted to drug taking can be reduced by their habits renders them a terrible source of danger to society. The other lesson is that the person who gives a good-natured certificate may be as dangerous as any criminal lunatic. As medical men know well at the present time, this is an age of certificates. A great deal of employment is taking place of persons who have not recently done much work, or whose industry has been in no sense continuous. The majority of these people require a character for honesty and efficiency, and the temptation to reproduce their own account of themselves in the signed certificate is very strong to all good-natured people; and so is the temptation to take narcotics for all the drug-addicted. If the person who takes the drug is a danger to society, what about the person whose amiable certificate places the drug-addicted in a position where particular danger to society can be inflicted?

The occurrence of canine rabies has been reported this week both in Devonshire and the Isle of Man, and the lesson for the population of England is the necessity for maintaining with the utmost regard the regulations with respect to quarantine of dogs arriving from abroad before they are admitted to the country; for the disease must have been imported, as it is many years since any cases occurred in Great Britain, Ireland, or the surrounding islands. The matter has importance when it is remembered how serious the incidence of rabies was some twenty years ago, when the authorities took a very strong line both as to the admission of animals from abroad and the muzzling of dogs at home. The public did not receive the muzzling orders with good temper, and their irritation was fanned by ignorant sentimentalists who took the line either that rabies existed only in the tortuous imagination of vivisectionists or that in no circumstances has man a right to be so cruel as to inconvenience his four-footed friend. A strong minister, Mr. Walter Long, was president of the Board of Agriculture at the time, having previously been Parliamentary Secretary to the Local Government Board. The muzzling orders introduced by him were stringently carried out, with the result, for example, that the number of cases in 1895 were 672, whereas by 1903 the disease was extinct. Since that date no case has occurred until the two that are now reported from Devonshire and the Isle of Man, and both localities are in close connection with the sites of war. The outbreak in the Plymouth district of Devonshire is surely connected with the transport work of this great port, and points to an infection from France, where canine rabies has existed for the last two years; indeed, during 1917 upward of fifty cases occurred in Paris alone. There are, of course, in the north and northeast of France large numbers of homeless, wandering dogs, and among these infection easily spreads. Now, there is among all soldiers and sailors, and

apparently air men, especially those of British origin, an almost superstitious regard for the affection of a dog. Officers on board ships frequently keep dogs when official status permits them to do so; the dog is the common friend in many regimental mess rooms, and is generally regarded by the men as a mascot; and not a few airmen take dogs with them when the nature of their work implies no risk to themselves or the animal. This means that a very large number of British dogs have a chance of obtaining rabies in France, and there seems no doubt that the English cases have been due to smuggling through quarantine of pet animals, one of which had become infectious. Smuggling of dogs is being guarded against by the authorities, and when detected the offenders will be severely punished.

It is rather an anachronism that in the twentieth century such a process as that known in the Lancashire, Glasgow, and Belfast weaving sheds as "shuttle-kissing" should exist. "Shuttle-kissing" is the act by which the weaver puts the side of the shuttle to his mouth and uses an inspiratory suction to draw the thread through the eye, and it is impossible to believe that an action so dangerous from a sanitary point of view could not be dispensed with either by the mechanical use of some crochet hook or by some alteration in the design of the shuttle enabling the weaver to push the thread through with his fingers. Old customs, however, die hard, and although an official report has been made to the Home Office and to the Local Government Board as long ago as 1912, the transmission of disease from person to person in weaving sheds is still possible, and still attributed to shuttle-kissing. The matter affects workers in both the cotton and the linen industries, and at the present moment the rapid spread of an influenza epidemic in Blackburn is alleged to have occurred through the prevalence of this habit. The local weaving association has turned to the medical profession for assistance, and has asked the medical officer of health for Blackburn to listen to a deputation on the subject, when no doubt the representations of the weavers will be brought through the medical officer of health to the attention of the Local Government Board. It must be allowed that in the official report of 1912, although the evidence was taken in a number of towns in Lancashire, in Belfast, and the North of Ireland and in Glasgow, there was no support forthcoming to the allegations that in certain particular instances the transmission of disease had ever taken place by "shuttle-kissing"; but the committee unanimously denounced the practice as objectionable, apart from the medical or public health aspect, on the ground of cleanliness of habit. It is unfortunate that the report did not go further, because no medical man can possibly believe that such an action as "shuttle-kissing," executed many times an hour in the environment of a weaving shed, can possibly be otherwise than dangerous. The action is not one of mouth suction, but is a sudden and forcible inspiration designed to carry the thread through the eye of the shuttle into the mouth of the operator, and in this way particles of dust, dye, fluff, and size, are carried through the mouth, the trachea, and bronchi, into the lungs. Whether concrete evidence is forthcoming or not, it is impossible to doubt that in this way disease germs have been disseminated. A single weaver may perform the act as many as 500 times in a day, while the working arrangements of the weaving shed may lead to the same shuttle being repeatedly "kissed" by different persons. Every medical man will hope that, whether the Blackburn weavers are able or unable to prove any connection between "shuttle-kissing" and an epidemic of influenza, their representations will lead to the disappearance of an unnecessary and unsanitary practice.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

ARRIVAL IN PARIS OF JAPANESE RED CROSS MISSION—DINNER TO DR. SCHURMAN OF CORNELL—ARRIVAL OF LELAND STANFORD UNIVERSITY UNIT—AMERICAN FUND FOR FRENCH WOUNDED OPENS NEW DEPÔT—AMERICAN JAZZ BAND ARRIVES IN FRANCE—CONGRESSIONAL COMMITTEE VISITS PARIS HOSPITALS—"RATHER FIGHT THAN EAT."

PARIS, September 3, 1918

THE arrival of a Japanese Mission in Paris in connection with the Red Cross is a noteworthy event. This mission is composed of Prince Tokugâwa, Dr. Ninajawa, jurist; Dr. Sawamura, chief surgeon; Mr. Yoshida, secretary of the mission; Mr. Flurusawa, secretary of the mission. Prince Tokugawa is a remarkable man. He is a Senator or Member of the Japanese House of Peers. He is of a family which dates back 250 years. An American treaty with Japan was made by his grandfather, an eminent Shogun acting as Viceroy of the Emperor. After visiting the French hospitals, the mission will accept the invitation of the American Red Cross to visit its hospitals.

One further step was taken last Wednesday evening in the development of the cordial relations which have ever characterized the Entente Franco-Americaine. This took the form of a dinner at the Cercle Volney, tendered to Dr. Jacob Gould Schurman, president of Cornell University, by the group of university men associated with M. Tardieu in the furtherance of Franco-American interests. In the absence of M. Tardieu the rôle of host fell to M. Piaux, the director of the Sixth Service of the Commissariat Général. The honor of welcoming the guest of the evening was assigned to M. Painlevé, Président du Conseil at the moment America entered the war, and a representative of the highest traditions of French scholarship. He dwelt eloquently upon the possibilities which the future presents of a rapprochement between France and America, not only in arms, but also in the intellectual world. In replying, Dr. Schurman paid tribute to the debt which the world owes both to French clarity of thought and to the achievements of French scholarship. The world, he said, still needs to go to school to France. Among those present were representatives of the faculties of the University of Paris, the American University Union, the American press, and the Commissariat Général.

The members of the Leland Stanford University Women's Unit, which has been sent to France for civilian relief work, has arrived in Paris. The unit has been temporarily assigned to the department of

military affairs, and some of the members are already busied as canteen workers, recreation hut workers, or hospital searchers. The unit, which is under the leadership of Miss Edith R. Mirrieless, will number fourteen when the other four members, now en route, reach Paris.

The committee of the American Fund for French Wounded is opening a big depôt at Clermont Ferrand, which has become such an extensive hospital center owing to its fine climate and central situation. The American organization is opening the depôt at the request of the French Service de Santé, with which it works in close cooperation. Materials and supplies of all kinds have already been sent to the new depôt, where a competent staff of A. F. F. W. workers has been installed. A temporary depôt was opened some time ago in that vicinity at Châtel-Guyon, but the fine premises which have been leased in Clermont-Ferrand will serve every purpose of the work, and the Châtel-Guyon work will be taken over by the new depôt. One of the new automobiles which has just arrived from America will be put into service at Clermond-Ferrand, and the new off-shoot of the Alcazar promises to be a success in every way.

Bringing gladness and joy to the hearts of many American wounded soldiers, the —th Artillery C. A. C. band and the Jazz band traveled over to Base Hospital No. 3 recently, and they truly succeeded in a worthy mission. Commencing at three o'clock, the artillery band, under the direction of the leader, Manuel Comulda, presented its program in one of the spacious courtyards of the hospital. Immediately after supper, occupying a portable stage in what was formerly the chapel of a huge monastery built in the year 1330, the jazz band, under the able management of Buck (Steve) Brodie, master of drums, bells, and traps, presented a ten-act vaudeville show that would easily get fifty-two weeks' booking on United States time. An odd and distinctive feature of this jazz band is that the individual members of the band are capable entertainers, each one doing a turn, culminating in an hour and a half of American vaudeville. The jazz band was fully costumed, and it was a picturesque setting they presented, against the color scheme and stained windows of the old French monastery.

It has been such a long time since any of the boys at the hospital had heard Broadway's favorite music that some of them were a bit impatient and anxious before the first number was given. From that time on, however, it was all cheers and whistles. Those boys who could not use their hands for applause, due to the "tilt" at the front, as some of them termed it, still had their lungs to fall back on.

Accompanied by Major J. H. Perkins, commissioner of the American Red Cross for Europe, thirteen members of Congress now in Paris visited American Red Cross hospitals Nos. 1, 2, and 5 yesterday afternoon. Many of the Representatives, who are from all parts of the country, found men from their districts and in several cases greeted by name wounded men from their home cities. The Representatives will go to the front before returning home by way of England. They reached France on July 17, and went to Italy from the port of arrival.

In recognition of the aid given by the American Red Cross to enable the completion of a tuberculosis sanatorium at Bligny, where 300 French officers and patients are now being cared for, a large tablet has just been placed in the entrance of the building. The hospital, which was opened on March 18, for the care of French officers and soldiers suffering from tuberculosis, was left unfinished when the war began in 1914. The Red Cross made a gift of 408,600 francs to enable its completion by the Service de Santé. At the end of the war it will be used for the care of tuberculous civilians. The tablet which has been placed in the hospital entrance reads: "In the fourth year of the great war, on March 18, this hospital was opened for French officers and soldiers through the friendly and generous cooperation of the American Red Cross."

Three American Red Cross men were wounded by German shells in the Franco-American counter-drive. They are Lieutenant J. L. Butterfield of New York City, who was leading an ambulance section; W. A. Fox of Buffalo, ambulance driver, who also was gassed, and Captain George B. Karr, representative of the Home Communication and Home Service Department with the —— Division. All the men will recover.

"To-day on the Ourcq, an American Division beat the First Division of the Prussian Guard." With these words M. André Tardieu, Commissioner General for Franco-American War Affairs, brought tremendous applause from the 150 officers and men of the American forces in France, who attended a dinner given in M. Tardieu's honor at the American University Union. The implied appreciation of the fighting ability of the American soldier voiced in the opening words of the French High Commissioner, is the opinion universal throughout France, and not to be wondered at, gauged by incidents like the following one, which is a live illustration of the time-old exclamation—"rather fight than eat."

The company cook of a front line regiment stood stirring a kettle of savory mixture as a Y. M. C. A. secretary came upon the scene. "This is a —— of a job for a grown man," he growled, as the secretary inquired if he could get a bite to eat. "My whole company is fighting up that road and I have to stay behind and wrestle a lot of pots and pans." The secretary remarked that some one had to do the job, for "an army moves on its stomach" and "the finger in the stew has as much to do with winning battle as the finger on the trigger." "That is all right for talk," replied the cook, banging the company dog with the dish towel, "but you know it ain't right for me to have to stay and assemble these here eats when all my pals are up there in the wheatfield running them Boches ragged."

Just then a company went by on the double, bound toward the thick of the battle. Two wounded men limped past in the opposite direction, going to the field hospital. "It is a great fight, boys," they said as the cook handed them a drink of water. "Best fight I ever saw," declared the one with the bandage on his head. "I would not have missed it for a farm. Just my luck to get a piece of shrapnel on the bean when we had the Huns going." The company cook could stand it no longer. He grabbed his rifle and tin hat and

started up the road toward the place whence came the chattering of machine-guns and rifle fire. "Hey, you," he called back to the Y. M. C. A. man, "just stick around and watch that —— slum for me, will you? The boys may want some dinner after they chase them Heinies back over the river." And the Y. M. C. A. man stuck and saved the "slum."

2. The "Instinct-Distortion" or "War Neurosis." Donald E. Corr.

1. The Kidney Function in 100 Cases of Hypertension.—W. C. Rappleye has made a study of the blood urea nitrogen, elimination of phenolsulphonephthalein, and a urine analysis on 100 cases of elevated blood pressure, using the figure of 150-155 mm. systolic pressure as the low value for selection. With but four or five exceptions, the patients were in apparently good physical condition and active; none showed any edema, dyspnea, fever or other compromising conditions. In this group of patients 70 per cent. showed blood urea nitrogen values below 16.0 mgm. per 100 c.c., 66 per cent. showed a dye excretion of 40 per cent. or higher, and 16 per cent. showed a value of 40 per cent. A slightly lower percentage was found in patients showing a higher blood pressure (systolic of 170 mm. or over, diastolic of 100 mm. or over). Twenty-eight per cent. showed both a urea nitrogen of 16.0 mgm. or over, and a dye excretion of 40 per cent. or less. Ninety per cent. of cases showing urea nitrogen of 16.0 mgm. or over had a dye excretion of 40 per cent. or less. Twenty-four of the cases showed a blood pressure over 160 mm., a urea nitrogen below 15.0 mgm. and a phthalein over 50 per cent. Rappleye points out that these findings do not seem to indicate that an elevated blood pressure, either systolic or diastolic, allows of a prediction that the kidney function is depressed, although in the series a considerable number do show evidences of such a depression in function, judging from the blood urea, phenolsulphonephthalein elimination and urine analysis. In the cases studied no relation was noted between a nephritic process and an elevated diastolic blood pressure. The author remarks that a discussion of the causal relationship of renal insufficiency and high blood pressure is beyond the scope of his paper, and adds that the opinion that hypertension results from impaired renal excretion raises the question whether or not the reverse may not frequently be true, that the impaired kidney function results from the hypertension with its concomitant vascular and perivascular changes, which tend to impair the nutrition and function of the kidney parenchyma. It may be that hypertension, while not signifying a nephritis, may denote that chronic nephritis will supervene.

4. Acidosis, Its Cause and Treatment.—Claude D. Waltz points out that acidosis is not in itself a disease but, like a fever, an incidence of disease. It is a symptom complex, complicating or resulting from certain diseased conditions, and the term is incorrectly applied to one single symptom. Where there is no symptom other than acetone in the urine, the term ketonuria or acetonuria should be employed. Van Slyke has defined acidosis as a condition in which the concentration of bicarbonate in the blood is reduced below the normal level, and Henderson describes it as any disturbance of the acid basic equilibrium whereby the power to resist acids in the body is lost. Acidosis exists in numerous diseases, but all tests may not be present. Acetone may be found in diabetes and in certain diseases of children, but not in chronic nephritis. All of these conditions may show an increased soda tolerance, etc. Therefore acidosis is not due to the same abnormal factor in each case. Arterial blood must be kept neutral or slightly alkaline. This is normally maintained by the removal of surplus acid radicals by the kidneys, and by the neutralization of the excess of acids, by body bases, and by ammonia, which, if not used, would be excreted as urea. When for any reason this balance mechanism breaks down, the alkali reserve of the body is lost, alkali starvation results, all nutritive functions become disordered, and coma or even death may follow. Waltz points out that whereas alkali therapy is certainly beneficial, like the treatment of fever with ice, it is merely symptomatic. Sodium bicarbonate may be given by mouth, by rectum, subcutaneously, or intravenously, the amount depending upon how quickly the symptoms of acidosis subside. A two per cent. solution is used subcutaneously and may be combined with potassium citrate or infusion of digitalis. A four per cent. solution is used intravenously. Transfusion by the syringe method of prealkalinized serum from a healthy donor has been used with success. Dyspnea and diuresis may thus be relieved, and occasionally there is mental improvement. The employment of carbohydrates is of decided benefit, either in the diet or in the form of glucose. In children especially, the regulation and control of the diet is important. The diet should be kept simple and the amount of fats reduced. The alimentary tract should be emptied with castor oil or calomel; one observer—Williamson—however, warns against calomel or mercurial douches because mercurial poisoning causes lesions such as are present in acidosis. In children when the periodic vomiting has ceased a low but not fat-free diet should be given. The prolonged use of alkali tends to produce acidity, either by stimulating acid secretion or by decreasing the alkaline output and, therefore, massive doses should not be given continuously. In some cases, after the administration of alkali, small, well diluted doses of acids may stimulate the body to produce its own alkali. In the acidosis of diabetes the diet should have three objects: (1) limitation of the acid products of metabolism; (2) conservation of the store of alkaline bases in the tissues and blood; (3) maintenance of the balance at normal level. It must be remembered that even though diabetic coma is due to acidosis, it is possible to correct the acidosis and return the blood to normal alkalinity and the patient still die in coma, due to the inability to correct the acidosis in the tissues as well as the blood.

3. Gunshot Wounds of the Knee-Joint with Septic Arthritis.—Major Arthur Neve points out that while most knee-joints which have been perforated by bullets or severely wounded by shell fragments, with injuries of the bones, may be saved by timely measures, it is the critical and threatening cases, which arrive in convoys from seven to fourteen days after being wounded, with well marked signs of infective arthritis, that tax the judgment of the surgeon as to the compatibility of conservation of the limb with safety to life. Infective cases with septic arthritis, especially when associated with bony damage, are infinitely more dangerous than the others. Whereas on a total of 845 cases of knee-joints of all kinds operated upon, of which many may have been free from septic arthritis, the amputations were 19 and the deaths 8.5 per cent., Max Page on a total of 70 cases gives 25 as infected, amputations 10, and deaths 5, or a mortality of 20 per cent. Neve's observations during 1916 and 1917 have led him to conclude: (1) That in the earliest stage of infective traumatic arthritis an attempt should be made by tapping and distending the joint with some antiseptic, such as flavine or iodoform emulsion, to abort the sepsis. (He points out that this is being successfully done in France and that good fixation of the limb is essential.) (2) That when sepsis is established *thorough* drainage is essential; anterior lateral incisions do not suffice; the Peck method is not successful. Suprapatellar, antero-lateral and postero-lateral incisions should be used in combination. (3) That if there is bone damage excision is desirable in most cases, and the bone surfaces may be kept apart. (4) That Carrel's method offers the only effective way of introducing an antiseptic fluid into the recesses of the injured joint. (5) That with other methods burrowing of pus very frequently occurs, with abscesses tracking up and down the limb and septic absorption; and amputation is apt to be performed too late, when the vital powers have succumbed to the prolonged strain and sepsis has become generalized with perhaps a fatal result.

1. The Differential Diagnosis Between Functional and Organic Paraplegia.—R. T. Williamson refers to the importance of differentiating between cases of malingering or functional paraplegia and those of organic disease. Certain reflexes are of the greatest service in the differential diagnosis and early recognition of organic disease. Especially valuable in early cases are the Babinski or Oppenheim reflex, and in many cases the loss of the tendo Achillis reflex. The chief difficulty occurs when the knee joints are not lost, and when ankle clonus, rectus clonus, and clasp knife rigidity are not obtained. In many cases the Babinski or Oppenheim reflex is diagnostic of organic disease; in others the plantar reflex is not of the Babinski type, and it may be lost or feeble, in which case the loss of the tendo Achillis reflex would be diagnostic of organic disease. The following are combinations of diagnostic importance, especially at the onset of a number of organic affections: Paresis with loss of the tendo Achillis reflex, as in early anterior poliomyelitis —chronic, subacute, or acute; Paresis with loss of the plantar reflex and loss of the tendo Achillis reflex (in many organic diseases); Paresis with double sciatica, and loss of the tendo Achillis reflexes, as in early cauda equina lesions; Paresis with loss of the tendo Achillis reflex, loss of vibrating sensation, and pains in the legs, as in early peripheral neuritis; Loss of the vibrating sensation with very slight incoordination and very slight paresis, with or without a Babinski reflex, as in early combined postero-lateral degeneration of the cord; Paresis, with Babinski reflex (in many organic affections); Paresis with loss of the vibrating sensation and Babinski reflex (in the early stages of several organic diseases of the cord); Root pains, or root symptoms, followed after a period of weeks or months by paresis, as in meningeal spinal tumour. In all these early combinations, Williamson points out that the knee-jerks may be obtained. In difficult cases, he has found the Babinski or Oppenheim reflex, the loss of the tendo Achillis, and the loss of the vibrating sensation whilst other forms of sensation are unaffected, of the most value in reaching a diagnosis.

6. The Value of Flavine. A Clinical Appreciation.—H. Mearns Savery is of opinion that many cases of failure are due to the improper use of flavine as an antiseptic. He draws attention to the following essential facts: (1) In the first place it is imperative that all affected parts should be reached as far as possible, and in order to carry this out thoroughly he always endeavors to introduce flavine solution by means of a hypodermic or dental syringe; (2) The flavine-soaked gauze should always be applied as wet as possible and any cavities filled up with the solution immediately before, and the part covered with a piece of mackintosh and wool; (3) A third important feature is the duration of the use of flavine—if applied continuously, a yellowish "pedicle" will appear on the surface of the wound in the course of a few days. This pedicle appears to be composed of leucocytes and fibrin. He notes that in several cases in which he has employed double saline solution (that is, 1.7 per cent NaCl) instead of the usual normal saline, this pedicle has failed to appear, and points out that the solution should not be used over prolonged periods as it seems to predispose to irritation of the skin and the appearance of a rash. Savery concludes that the best results from flavine are obtained from its early application and that the appearance of the pedicle is an indication that a change to eusol, brilliant green, magnesium sulphate, or other antiseptic should be made about the fourth day, after which flavine should be given once in every three days. In his experience this method has given great satisfaction. He emphasizes the point that it should be more generally recognized that it is the *early* effect of flavine, which follows within several days after its application, which is the most important feature, and that proper advantage should be taken of this fact.

The Treatment of the So-called Surgical Tuberculoses in Special Establishments and Hospitals.—A. Bier maintains that hospitals situated in the plains are quite as

effective for the treatment of these cases as when situated in high altitudes. It is now known that the sun at an altitude is not essential, as very satisfactory results from heliotherapy can be obtained in the plains, particularly when combined with radiotherapy, quartz lamp, etc.

The Genesis of Gastric and Duodenal Ulcer.—R. Ehrmann points out that the site of predilection of gastric ulcer is in the areas poor in folds. Other factors of a mechanical order undoubtedly play a large part in the etiology. Thus chronic trauma such as shocks, hemorrhage, external compression, too hot or too cold food, etc., may be the cause of erosions which transform into chronic ulcers from the action of the gastric juice. Radiographs of stomachs filled with barium or deformed by external factors (corsets) illustrate the conception of the writer. As to pain, Ehrmann rejects the usual explanation of dragging on the celic plexus and the irradiations and Head's areas. He admits a local sensitiveness of the ulcerated area, exaggerated by the gastric juice or peristaltism.

Circulation of Extracardiac Origin.—H. Kohn rejects certain arguments brought forward to back up the theory that the blood not only circulates by the propulsive action of the heart, but also from a sort of vascular peristaltism (Bier, Hasenbrock, and others). The study of a case of aneurysm with probable thrombosis of the vessels of the base of the neck showed that the pressure is distributed, according to all probability, exclusively by the cardiac propulsive action. However, the writer does not deny the possibility of a vascular peristaltism, and he simply limits himself to criticize the arguments of certain writers who defend this new theory.

The Treatment of Acute and Chronic Empyema, Particularly Empyema Following Wounds of Warfare.—Hartert first offers the following statistics from the viewpoint of the transformation of pulmonary wounds into empyema:

Bullet wounds	51 cases, with 15 empyemas, =	30 per cent.
Shell wounds	33 cases, with 18 empyemas, =	55 per cent.
Shrapnel wounds	7 cases, with 4 empyemas, =	57 per cent.
Stab wounds	2 cases, with 2 empyemas, =	100 per cent.

The writer treats all acute empyemata by rib resection in preference to simple incision, because the drainage is better. The drainage tubes are sutured to the borders of the cutaneous incision and in the wound so as to make it hermetic. By so doing a continual aspiration results which maintains the physiological negative pressure in the pleural cavity. Chronic empyema should be treated in the same way. The writer was able to obtain a complete occlusion of 20 cavities out of 23 treated. The three which did not completely obliterate closed down appreciably. The writer gives the following general rules of treatment: (1) Measure regularly the secreting cavity by filling it with fluid, in order to follow its decrease in capacity; (2) the hermetic fixation and introduction of the drainage tube, which should be a rigid one. When dealing with a fistula it is to be first dilated, and after the tube is inserted it will contract and hold the tube tightly or nearly so. Irrigations with oxygen water. Aspiration is assured by a vacuum bottle. Hartert thinks that an aspiration which realizes 5 liters in 24 hours is sufficient. This treatment reduces considerably the number of cases with fistula as an ultimate result of operative treatment. [The writer gives no credit to Prof. Revilliod of Geneva, who first introduced continued aspiration of empyema in 1885 and employed it successfully in a very large number of cases. The method is well known to non-German physicians, but the writer would lead one to suppose that the method originated with him.]

The Treatment of Hemorrhoids by Adrenalin Injections.—H. Krukenberg obtains a rapid retraction of hemorrhoidal tumors by giving a single injection of 0.5 cc. This dose will reduce a hemorrhoid the size of a walnut within a week's time. A hemorrhoid the size of an apple was greatly reduced by fifteen injections given during seven weeks. The drug is injected under the mucosa, as is done for anesthesia of the mucous membrane.

On Regeneration of the Joints.—E. Payr describes in this installment of his article continued from the issue of July 25 the process of neoformation which, in cases of unreduced dislocation, finally ends in the formation of a glenoide cavity as a result of periosteal proliferation. In the case of dislocation of the femoral head a neoformed ligamentum teres arises, first composed of granulation tissue and at length becoming tendon. The negative pressure developed during movement is the efficient cause of the development of the new joint. Excision of joints for surgical reasons have been replaced by most astonishing transplantations. Thus the upper end of a femur removed from a cadaver has been successfully grafted. The muscles then become spontaneously fixed on the bone at their proper points of insertion. The portion of grafted bone already played an important mechanical part long before it was possible for it to have been replaced by living tissues. Payr also studies the process of repair in various forms of arthropathies and arthritides. He compares the data obtained between pseudoarthrosis and neoarthrosis; the formation of the tendon-sheaths is compared to that of the serous bursæ and then he gives a general review of the results obtained by animal experimentation.

The Doctrine of Constitutional Conditions and Its Application to the Problem of Chlorosis.—Naegeli again reverts to his conception of chlorosis considered as an endocrine disturbance. After a critical review of the opinion that this affection is a constitutional hypoplasia, the writer emits that of the influence of the ovarian function and more particularly of the interstitial gland. The correlated disturbances of the suprarenal apparatus may support this point of view (suprarenal hyperfunction). The critical review of the subject given by the writer is the most convincing part of his contribution, as the portion given up to the writer's theory is not founded on sufficiently well developed arguments.

A Case of Sympathetic Ophthalmia Following a Wound of Warfare.—J. Meller reports the case history of a soldier in whom a shell shot produced a wound of the eye with the presence of fragments in the organ. These were removed and the favorable evolution of the wound led the surgeon to give up the idea of doing an enucleation. Then the vision did not improve, and four weeks after the receipt of the injury enucleation was done. Twenty-five days later an iridocyclitis developed in the fellow eye which had been quite normal. The evolution of the process was, however, benign The writer particularly insists on the following peculiarities of the case: (1) The traumatized eye was not infected and lost its function from cicatricial contraction resulting from the tracts made by the bits of missile and organized blood clot; (2) enucleation undertaken at a time when the fellow eye was in perfect condition did not prevent the occurrence of sympathetic ophthalmia. He concludes that the sympathetic ophthalmia was in no way connected with an infection, it being the result of a change in the iris and ciliary body of the injured eye. Finnally, Meller advises against a too conservative treatment of ocular wounds.

Ether and the Present War.—In a discussion before the Société de Chirurgie, Paris, in April, Thiery stated that from 20 to 25 deaths annually in Paris hospitals are due to chloroform narcosis. He had been one of the first in Paris to change to ether, in 1890. Tuffier has long been a partisan of ether. Ed. Schwartz always uses it save in certain contraindications. The society as a body protested against some remarks by Regnier to the effect that chloroform could be made perfectly safe.—*La Presse Médicale.*

Book Reviews.

STUDIES IN THE ANATOMY AND SURGERY OF THE NOSE AND EAR. By ADAM E. SMITH, M.D., Past Chief Medical and Sanitary Officer, Nile Reserve Works, Assuan, Egypt; Past Instructor in Operative Surgery, Columbia University Medical College; Past Attending Surgeon, German Hospital, O.P.D., New York City. Price, cloth, $4 net. New York: Paul B. Hoeber, 1918.

THIS book, dedicated to the late Dr. Frank Hartley, deals with the anatomy of the nose and ear from the surgical standpoint and is divided into six sections, covering distinct but correlated phases of the subject. The captions are: I, The Importance of Nasal Breathing; II, Some Suggestions on the Treatment of Intra-Nasal Conditions; III, A Contribution to the Anatomy and Surgery of the Nose and Its Sinuses; IV, Anatomical and Surgical Desiderata in the Exposure and Removal of the Pituitary Gland; V, Postural Treatment of Otitis Media and Mastoiditis; and VI, A Contribution to the Anatomy and Surgery of the Temporal Bone. These studies form a valuable addition to the literature of nose and ear surgery. The author displays considerable originality together with a profound knowledge of his subject and is, in addition, an adept at descriptive writing. The book is remarkably well illustrated, the illustrations having been made directly from dissections prepared by the author, and drawn under his supervision by Mr. Martin Peterson. When to these excellent illustrations, which are often accompanied by diagrams emphasizing the salient features, is added the author's unusually terse and lucid descriptions, it is evident that the book should be of great value to the student of this complicated and confusing region. The specialist also will find in the text much that is new and well worthy of his attention.

THE TREATMENT OF WAR WOUNDS. By W. W. KEEN, M.D., LL.D., Major, Medical Reserve Corps, U. S. Army; Emeritus Professor of Surgery, Jefferson Medical College, Philadelphia. Second edition. Reset. 12mo of 276 pages, with 53 illustrations. Price, $2 net. Philadelphia and London: W. B. Saunders Co., 1918.

IN our review of the first edition of this book we said that it should be of considerable value to surgeons about to have their first experience in war surgery, though it was far from being as exhaustive as might be desired. In this edition many of the defects which we had in mind have been remedied. The book has been largely rewritten and entirely reset, while more than 100 pages of new material have been added, so that it is almost a new book. More space has been given to such subjects as shock, the Carrel-Dakin and other methods of treatment, to fractures, tetanus, wounds of the head, chest and joints, and to gas gangrene. The lessons that have been learned during the past year are constantly brought out. This applies especially to the surgery of the chest, where wounds of the lungs are now operated upon with as little concern and with much more chance of success than are those of the abdomen; to the surgery of the joints; and the treatment of wounds of the soft parts. The first edition contained reprints of a number of personal letters giving the results of experience of prominent surgeons in various methods of treatment and other matters. About 25 pages are devoted to reprinting personal letters in this volume; some of these, particularly that of Sir Anthony Bowlby, being especially instructive. As the book now stands it certainly cannot fail to be of great value not only to those entering the Service but also to any surgeon in civil practice who has to do with traumatic cases.

FARMERS' CLEAN MILK BOOK. By CHARLES EDWARD NORTH, M.D., Director North Public Health Bureau; Secretary, Commission on Milk Standards of the New York Milk Committee, etc. New York: John Wiley & Sons, 1918.

THIS little book comprises an account of the methods of handling and marketing milk, milk inspection, dairy inspection, popular beliefs and their foundation in fact, etc. Special chapters are given on the udder, barn dust, installation for the milk industry, milking, cooling and sterilization, high grade products, the dairyman as an individual, dairy inspection cards, dairy arithmetic, etc. Nothing is omitted in the way of illustrations, statistics and documents used in exhibits. The work is naturally of the greatest value to one in any way interested in milk problems.

EMERGENCIES OF A GENERAL PRACTICE. By NATHAN CLARK MORSE, A.B., M.D., F.A.C.S., Surgeon to Emergency Hospital, Eldora, Iowa; District Surgeon Chicago Northwestern Railway, Minneapolis & St. Louis Railway; Ex-President Iowa State Association of Railway Surgeons; Ex-Vice-President Pan-American Congress; Fellow American Medical Association; Member of the Society of Clinical Surgeons of North America; Author of "Post-operative Treatment." With 251 illustrations. Price, $4.50. St. Louis: C. V. Mosby Company, 1918.

THE author has collected within a comparatively small compass a large amount of information on practically all the emergencies met with in the course of a general, and, in some instances, a special practice. The data have evidently been gleaned from an extensive experience in work of this character, and are presented in a readily assimilated form. The book is divided into twelve chapters, covering 441 pages. The first chapter is devoted to general topics, such as emergency instruments and outfits, principles of asepsis, closure of wounds, use of adhesive plaster, and kindred procedures. Chapter II takes up the removal of foreign bodies from the nasal passage, pharynx, larynx and trachea, ears, eyes, urethra and bladder, rectum and stomach. In connection with the removal of bodies from the trachea and bronchi no reference is made to the pioneer work done in this country by Chevalier Jackson on bronchoscopy. In Chapter III the author considers the treatment of asphyxiation from drowning, smoke, gas, and electric shock, with a description of mechanical devices for artificial respiration and methods of using the same. In speaking of the treatment of various kinds of gas poisoning, the advisability of blood transfusion as a *dernier resort* is referred to, and considerable space is given up to a description of Crile's direct method, now long obsolete, but no mention is made of the simpler and now universally used syringe-cannula method, or the use of citrated blood with the gravity apparatus. Chapters IV and V are concerned with surgical emergencies. A long list of injuries and wounds of all kinds is given, with their appropriate treatment, including some acute conditions as appendicitis, peritonitis, tubal rupture, strangulated hernia, intestinal obstruction, etc. Next follows a short chapter on the commoner medical emergencies, viz., hemoptysis, diabetic coma, cerebral hemorrhage, angina pectoris, acute indigestion, intestinal, renal and biliary colic, laryngitis stridulosa, ophthalmia neonatorum and hiccough. Chapter VII contains a miscellaneous collection of accidents, diseases, and abnormal states such as ptomaine poisoning, burns and scalds from various agencies, paraffin method of treating burns, thermic fever, trichiniasis, rabies, tetanus, convulsions of children, frost bites, snake bites, and bites from insects and animals, retention of urine, and finally the extraction of teeth. The author here displays a versatility in the handling of these subjects which does credit to his wide experience. Fractures, dislocations, and amputations are considered in Chapters VIII and IV in some detail. Chapter X, on obstetric emergencies, takes up abortion, retention of placenta, Cæsarean section, placenta previa, forceps delivery, inversion of the uterus, puerperal eclampsia, prolapse or presentation of umbilical cord, uterine hemorrhage in young girls. The last two chapters are devoted to poisoning from drugs used as medicines, acids and alkalies, and ordinary poisons. The list covers practically all of the commoner substances, but fails to include the newer chemicals employed in the manufacture of explosives and dyestuffs, as, for instance, trinitrotoluol, nitrogen oxide, mustard gas, and aniline.

On the whole, this book is a good one. A few typographical errors are met with here and there. The volume is profusely illustrated and is printed on high-grade paper in clear, legible type. Topics are grouped under leading captions and a detailed index makes quick reference an easy matter. We can recommend this book to anyone interested in this particular line of work.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-Third Annual Meeting, Held at Philadelphia, May 16, 17 and 18, 1918.

THE PRESIDENT, DR. JOHN G. CLARK OF PHILADELPHIA, IN THE CHAIR.

(*Concluded from page 658.*)

Elusive Ulcer of the Bladder; Further Notes on a Rare Type of Bladder Ulcer, with a Report of Twenty-five Cases.—Dr. GUY L. HUNNER of Baltimore stated that this type of ulcer was first described by him in 1914. The lesion consisted of a chronic inflammatory infiltration of all coats of the bladder wall. The areas of active ulceration discovered by cystoscopy were always superficial and usually minute, and an area of congestion seen on one examination might be absent at the next, but would be found later if repeated examinations were made; hence the name elusive ulcer. The symptoms were usually of the most extreme type characterizing bladder ulcer in general. The errors in diagnosis in the past had been due to the elusive and minute character of the mucosa lesion, to the examination of the urine, or to the failure to place proper emphasis on the finding of a few leucocytes or erythrocytes in the urine, and to the misleading character of some of the referred extravesical pains.

Systematic treatment with strong silver nitrate solutions, or stick silver, or actual cautery, would give comparative relief to many of these patients, but the only cure thus far discovered was the complete excision of the involved area.

Dr. JOHN G. CLARK of Philadelphia said that one of his patients, who had gone the rounds and had been treated by several doctors without permanent relief, fell into the hands of Dr. Hunner. He was present at the operation performed by Dr. Hunner, the ulcer was demonstrated to him, and its excision was followed by a remarkable cure. Since that time he had seen three cases of ulcer of the bladder, in all of which the diagnosis was easily made with the cystoscope, and excision of the ulcer bearing area was followed by splendid results.

Dr. PHILANDER A. HARRIS of Paterson, N. J., recalled the case of a girl, thirteen or fourteen years of age, who had not begun to menstruate. Her hymen was untorn and she showed no signs of any infection. Examination of the bladder was difficult by the direct method because she was unable to retain more than three ounces of urine. Night or day the bladder had to be emptied. She had a great deal of pain and, not being satisfied with the nature of the pathology, he resorted to distensions of the bladder with salt solution, as advised by Dr. Kelly in years past. After about twelve applications he lost sight of the patient, but subsequently learned that she was able to pass urine in eight or twelve ounce quantities for about two years, then she reappeared. She was now twenty-four years of age and married. He did everything he could to cure her, but she was so far from cured that she was only able to retain two or three ounces of urine at a time. He asked Dr. Hunner whether he had had experience with distention of the bladder according to the practice of Dr. Kelly.

Dr. CHARLES A. L. REED of Cincinnati asked Dr. Hunner to discuss the question of etiology in closing, which was especially important in view of his failure to find bacteria in the urine following operation. He also asked Dr. Hunner whether or not there had been any recurrence following excision of the ulcer.

Dr. LEWIS S. MCMURTRY of Louisville asked Dr. Hunner if he had tried other and more conservative methods of treatment than excision. Excision seemed a severe operation for a benign ulcer.

Dr. EDWARD H. RICHARDSON of Baltimore said that a striking thing in one case of ulcer of the bladder he saw, and this obtained in other cases, was that the clinical picture and the bladder pathology were out of all proportion to what one saw on cystoscopic examination. In this particular instance, when he looked into the bladder, although he searched the bladder many times with the utmost care, he failed to discover any lesion. The patient was not one to suggest a neurotic individual. He finally called Dr. Hunner in consultation and operation was decided on. When the bladder was opened it was found that fully two-thirds of the bladder wall was involved in the pathological change. Not only was the mucous membrane edematous, but the musculature of the bladder was thickened to the extent of fully three times that of normal. The woman made a splendid recovery and now voided urine normally.

Dr. EDWARD P. DAVIS of Philadelphia said it was his fortune to have under his care during pregnancy and labor one of Dr. Hunner's most successful cases. The history was that the patient became infected by catheterization after a previous operation. He attempted nothing whatever concerning the bladder. He did not examine it, but watched the case with very great interest. Ordinary microscopic examination of the urine showed but a few red and a few white cells, but this was so commonly seen among pregnant women that it gave rise to no suspicion. The patient passed through a more or less miserable pregnancy, went into labor, the normal course of dilatation took place, she was delivered by forceps, passed through a condition of comparative neurasthenia and shock for which no adequate cause could be found. Her disability was out of all proportion to any vesical symptoms connected with the parturition. Her cure by Dr. Hunner of the bladder ulcer was certainly one of the most satisfactory he had ever known. It might interest the members of the Society in this connection to know that so far as this one observation of pregnancy and parturition went, there was neither an increased severity of the lesion nor did it in the slightest degree tend to make it better.

Dr. CATHERINE MACFARLANE of Philadelphia stated that her experience with ulcer of the bladder was limited to three cases which occurred during the past year. The lack of proportion between the severity of the patient's symptoms and the insignificant bladder lesion and trifling urinary findings had been emphasized. A diagnosis was much better made by the clinical history than by the laboratory findings or physical examination. Complete relief followed the operation of excision in these three cases.

Dr. W. F. SHALLENBERGER of Atlanta, Georgia, stated about two months ago he saw his first Hunner ulcer. He saw the patient some years before and at that time the urinary findings were negative. Cultures were also negative. He overlooked ulcer of the bladder at that examination. The patient then gave a history of bladder distress of some ten years' duration. She had been treated by a dozen different men from time to time, and had been operated on by one of them for a pelvic condition without any marked relief. Occasionally treatment would afford temporary relief. In this particular case there were three ulcers of the bladder, one 2 mm. in diameter and two smaller ones near by, situated about 3 cm. above the internal urethral orifice back of the symphysis. Wide excision of the ulcer bearing area had given the patient complete relief from her symptoms.

Dr. HUNNER, in closing, said he had tried conservative methods of treatment in these cases. He had used the high frequency current in a few of them, but it caused them so much afterpain that they absolutely refused to have it continued. Strange to say, the actual cautery wire gave fairly good temporary results. He depended mostly upon silver nitrate in one form or another in treating these bladder ulcers, and they could be kept reasonably comfortable by one or the other method. Excision of the ulcer bearing area was the only thing that afforded permanent relief, but this excision must be complete. In the case of a girl there was a recurrence shortly after she returned to her home in Birmingham. Quite recently three cases had come to him that he was inclined to think had recurrences. In two of them a less extensive excision of the ulcer bearing area was done than usual. As to the etiology, there was one case described by Dr. Davis of bladder infection after catheterization after an Alexander operation. It was the only case where he had anything to point to the etiology. Most of the patients he had had were unmarried women and showed no evidence of gonorrhea. We were still at a loss to know the etiologic factors.

The Bladder of Women After Operation.—Dr.

Arthur H. Curtis of Chicago reviewed briefly the work reported two years ago, which he believed demonstrated that postoperative catheter cystitis was really urinary tract infection caused by residual vesical urine. An essential feature in the treatment of postoperative cases had been the prevention of urine stagnation in the bladder. Four hundred and sixty-five consecutively operated patients had been managed as follows: all who complained of vesical distress were catheterized. Also even when the power to void urine was present, catheterization was performed if residual urine was suspected. Furthermore, those patients who had required catheterization were thereafter catherized once daily immediately after urination, as long as residual urine was obtained. At the time of catheterization 15 c.c. of ⅛ per cent. silver nitrate was instilled before the catheter was withdrawn. Medication consisted of hexamethylenamin in amounts sufficient to maintain a positive formalin test. In the presence of alkaline urine, acid sodium phosphate was added. Those who showed idiosyncrasy to hexamethylenamin, or whose urine yielded no formalin, were treated with alkalies. In the presence of urinary tract infection, meats were permitted but twice weekly. Seasonings of all sorts were forbidden, salt excepted. Sugar, sweets, and pastry were limited. Before this method of treatment was instituted many operated patients returned with urinary tract distress and infection. Under the present plan postoperative bladder troubles had disappeared. He had found that many pregnant women failed to empty the bladder completely. He believed that retention of vesical urine was a factor of the utmost importance in the etiology of pregnancy pyelitis. It was therefore urged that obstetrical patients be tested for residual urine whenever carefully collected specimens revealed pus and bacteria. Through judicious cauterization, immediately after urination, it was believed that these patients could often be saved from the danger of pyelitis. The plan of catheterization for residual urine had likewise been extended to tabetic cases. A patient with well advanced disease, afflicted with intense vesical disturbances, had apparently been permanently relieved. It was thought that the failing bladder of tabes might be reeducated through the use of the catheter combined with intensive antisyphilitic therapy, provided treatment was undertaken at a time when moderate function still remained.

Dr. John A. Sampson of Albany stated that he found after a radical operation for carcinoma of the cervix that severe cystitis was a common complication, and he attributed the bladder disturbance to interference with the blood supply and with its function. Some of these patients in whom there was incidentally a vesico-vaginal fistula were not troubled with cystitis, and he even went so far as to suggest that possibly in these severe cases the formation of a vesico-vaginal fistula temporarily would obviate the cystitis. One of the most important ways of treating a severe cystitis was that carried out by Dr. Kelly in his clinic, namely, establishing free drainage and rest.

Dr. Guy L. Hunner of Baltimore agreed with the essayist that retention of urine was perhaps the chief factor, and this was most often due to postoperative overdistention of the bladder. It would seem to him that interference with the circulation and traumatism to the bladder itself did not have an important bearing on the question of postoperative cystitis; but if these patients were allowed to go on after operation with overdistention of the bladder we might get a partial paresis, which might last for several days or weeks, creating a most favorable condition for infection to take place.

Dr. J. Riddle Goffe of New York City asked Dr. Watkins about the treatment after washing out the bladder.

Dr. Watkins, in closing for Dr. Curtis, stated in reply to Dr. Goffe he always passed a catheter as soon as the patient had any distress. He never allowed a patient to have distress in the bladder on account of the presence of urine. After a patient had been catheterized every two or three days, he also catheterized once a day after that until he was sure she was not carrying an excess of residual urine. Daily catheterization was stopped as soon as he was convinced that the patient was not carrying a large amount of stagnant urine.

Dr. Leroy Broun of New York City asked to what extent residual urine was found and in what quantity.

Dr. Watkins replied that almost invariably a crippled bladder was found in women who had to be catheterized every two or three days. The case that required catheterization very seldom carried stagnant urine.

Tubal and Ovarian Hemorrhage; Its Etiological Relation to Pelvic Hematocele and Extrauterine Pregnancy. Dr. J. Wesley Bovee of Washington, D. C., said that trauma played a part in producing these hemorrhages, as in cases reported by Freeman, Primrose and many others. Hemorrhage from the Fallopian tube might occur from general conditions that similarly affected other tissues. Venous stasis from circulatory disturbances or pressure from tumors might be reasonably included in a list of its causes. Ovarian hemorrhage might be confined within the ovary, constituting one or more hematomata, or it might take place into the peritoneal cavity, producing, if abundant, a hematocele. No other organ of the body was so frequently the seat of hemorrhage as was the ovary, and a large amount of literature had been written on the pathology of the ovary in ovarian hemorrhage. Stromal hemorrhage was commonly preceded by infection of the ovary. In but few cases had correct diagnoses been made before operation or autopsy. As to treatment, in the milder forms of the condition rest and anodynes might meet all indications. In the severer forms the same rules applied as were employed in the treatment of ectopic pregnancy.

Further Study as to the End Results of the Conserved Ovary.—Dr. John O. Polak of Brooklyn, New York, from a study of seventy-three reoperations on patients in whom one or both ovaries were conserved, drew the following conclusions: "(1) Routine conservation without due consideration of the ovarian and contiguous pathology as it exists in the individual case is not good teaching. (2) Regeneration of the conserved ovary depends largely on the type and duration of the existing infection and the condition of the tunica of the individual ovary. (3) Even where the most detailed technique is observed the ovarian circulation is impaired. (4) The retained ovary without the uterus is always a focus for possible trouble. (5) The life history of the retained ovary is of short duration and the trophic influence of the diseased ovary has been overestimated. Finally, a cured patient has few nervous symptoms."

The Effect of Hysterectomy Upon Ovarian Function.—Dr. Edward H. Richardson of Baltimore drew the following conclusions: "(1) The ovary is a glandular organ of complex function, our knowledge of which is at present far from complete. (2) The uterus is not essential to a continuation of ovarian function, except as regards menstruation and reproduction. (3) The advocates of total ablation have not furnished convincing evidence of the correctness of their contention. (4) The disturbances of ovarian function attributed to hysterectomy are partly those associated with normal menstruation and partly those arising from damage to the ovary through operative trauma or disease. (5) The weight of evidence furnished by anatomical experimental and clinical investigations is overwhelmingly in favor of retention of sound ovaries both before and after the menopause age."

Dr. Howard A. Kelly of Baltimore believed in practice it was best to conserve the ovaries or as much of healthy structures as might be retained in women who were under forty, and in women of forty or forty-two it was best not to be so conservative. In the past we had decidedly overdone conservatism. We had done entirely too much. If we could conserve either ovary and a portion of the uterus and keep up menstruation, if only for a year or two, it was a great advantage.

Dr. Walter W. Chipman of Montreal said that every effort should be made to care for the circulation of the ovary that was left behind. Within the past he pleaded guilty of not being sufficiently careful in this respect. He certainly was conservative in the matter of the ovary. If we could tell a woman after an operation that her sexual organs were preserved it was a great psychological comfort to her. It went without saying that where the ovaries were diseased they should be removed. He no longer resected diseased ovaries.

Dr. Henry T. Byford of Chicago stated that one important thing was not to pay so much attention to the symptoms of the menopause. It was well not to enumerate these symptoms to patients, but give them ovarian substance or extract, and when they knew they were getting it the psychological condition would be kept up, which was so necessary in these cases, and there would be less operating. With a little treatment and advice along the line of Christian Science he did not think we would have to do quite so much surgery.

Prolapsus Uteri.—Dr. Walter W. Chipman of Montreal gave a short description of the true pelvic floor, in order to identify the essential supports of the uterus and to get a correct understanding of the treatment of its prolapse. In the treatment of prolapsus uteri, he stated that in selected cases, especially during the child bearing period, vaginal pessaries, properly fitted and cared for, had a distinct use. It was, however, the surgical treatment of this condition of which he desired to speak. In all essentials, cystocele, prolapsus uteri, and rectocele was a hernia. The diaphragm of the true pelvic floor had yielded. Its two halves had been pushed aside or torn asunder, and between them the bladder, the uterus, and anterior rectal wall were dislocated and descended. These organs slid downward and in their descent gradually inverted the vagina. This surgical treatment, as in all hernias, aimed at a radical cure, and here he urged that the terms anterior and posterior colporrhaphy be definitely discarded, since these names no longer accurately expressed the surgical measures that were undertaken. A much more adequate and expressive term was a radical cure of the cystocele or rectocele. He then described at length and in detail the operation that he performed.

A Vaginal Hysterectomy Technique for the Cure of Prolapse of the Uterus When the Removal of the Uterus Is Necessitated, with Special Reference to Lapping of the Vaginal Fascia in All Forms of Vaginal Prolapse.—Dr. Dougal Bissell of New York City stated that the usual curved incisions were made about the cervix at the vaginal mucosa junction and the mucosa freed. Anteriorly the bladder was completely freed from the vaginal wall and the cervix, the peritoneal cavity opened, the corpus delivered anteriorly, and the uterus removed from above down. Throughout the operation the posterior tissues formed a barrier and prevented the intestines from protruding into the vagina and the blood from entering the peritoneal cavity. They were cut last. The two anterior vaginal wall flaps were trimmed longitudinally to the extent required, and that to the left of the operator was completely denuded of its mucous membrane. The free cut margin of the denuded flap was now anchored under the undenuded flap by four mattress sutures to the stable portion of the vagina on the opposite side. The undenuded flap was anchored by three or more interrupted and continuous sutures to the stable portion of the vagina along the opposite sulcus. A chromic gut suture No. 2 penetrated and was tied about each cut cardinal ligament, leaving two free strands. One strand of each suture was utilized as a running stitch along the cut surface of the posterior vaginal wall, and the other tied to approximate the cut ends of the cardinal ligaments. The latter sutures were again made to penetrate the lower margin of the newly constructed anterior vaginal wall and tied to the sutures penetrating the posterior vaginal wall. When in cases of procidentia uteri it was found advisable to retain the uterine body and amputate the cervix, the initial technique was identical to the above, also the lapping of the fascia. The sutures anchoring the mucosa over the cervical stump were placed so as to make the mucous edges approach each other in a vertical direction, instead of a horizontal direction according to Emmet.

To correct a rectocele, a transverse incision was made through the rectovaginal fascia into the cellular area between the rectum and the vagina. The tissues were freed laterally and longitudinally, and as the freeing was continued longitudinally a median incision was made through the fascia and mucosa, extending to within a short distance of the cervix. The vaginal flaps were prepared for lapping and were anchored in practically the same way as described above in lapping the flaps of the anterior vaginal wall. One of the great advantages of the fascial lapping technique here described, whether dealing with a cystocele or rectocele, was that the finding and following of only one line of fascial cleavage was necessary. When this line of cleavage only was followed a minimum amount of bleeding resulted, but when both lines of fascial cleavage were followed a maximum amount of bleeding occurred, which under certain conditions might terminate seriously. Another important advantage in thus utilizing the fascia without disturbing its continuity was that a minimum amount of disturbance in its circulation was occasioned and when the flaps were anchored the circulation in them remained practically unimpaired. Too much emphasis could not be laid on the desirability of trimming the vaginal flaps to apparently an excessive degree. Failure would occur if the effect produced after the completion of the operation was not that of overcorrection.

Cystocele; a Review of the Literature with a Further Preliminary Report of an Operation.—Dr. Reginald M. Rawls of New York City said that from the time of the Egyptians (1550 B. C.) to the Arabian school, the ancients possessed a considerable knowledge of the mechanical and local medicinal treatment of prolapsus uteri. However, Hippocrates and Soranus referred to successful vaginal hysterectomies when the uterus could not be replaced or had become gangrenous. The treatment in early modern gynecology, up to the first quarter of the last century, was also principally medicinal and orthopedic, until 1828, when Diffenbach performed anterior colporrhaphy for prolapsus. He was followed in 1833 by Fricke and in 1849 by Hugier. In 1853 Baker Brown utilized, in addition for his denudation, the vulva and perineum. In 1856 Sims devised an improved method of anterior colporrhaphy by his oval, V—, and trowel denudations. Emmet in 1862 made the V into a triangle and in 1869 devised his prolapse operations by utilizing the fascia to support the uterus and bladder. In 1874 Simon and Hegar simultaneously devised an operation on the posterior wall, claiming this would not only support the uterus, but also the anterior wall and bladder. They were followed by other operators, some of whom also utilized both anterior and posterior wall and LeFort made a longitudinal septum in the vagina.

In 1887 Hadra made a decided advance when he used flap splitting and elevation of bladder. Saenger in 1888 used a similar method and was followed in 1892 by Mackenrodt and Duhrssen, who devised vaginal fixation. In 1895 Freund first delivered the uterus into the vagina and was followed in 1899 by Watkins, Wretheim, and Schauta, who reported the operation of transposition of uterus and bladder. Various other vaginal operations had been devised by Doleris, Reynolds, Hirst, Alexandroff, Tweedy, Dudley, Jelett and others, and among abdominal operations for cystocele might be mentioned those of Byford, Stone, Lawson, Dickinson, Polk, and DuBose. In 1902 Goffe devised a vaginal operation for mobilizing the bladder and elevating and supporting the bladder by suturing it to the uterus and broad ligaments. In the early part of the present century various operations had been reported based on anatomical studies. Operators who attempted to restore the fascial sling of the anterior wall were Kreutzmann, Sippel, Petersom, Violet, Martin, and Frank. Martin demonstrated by his recent anatomical investigation that cystocele was due to a lack of fascia and connective tissue at the base of the bladder and showed that by dissection of the anterior wall the fascia could be demonstrated, and by suturing the edges in the mid-line the cystocele would be obliterated. In the March, 1918, number of the *American Journal of Obstetrics* the author reported a technique devised independently by him of overlapping the fascia and reattaching it to the uterus by transverse mattress sutures, which were so applied as to carry the underlapped fascia smoothly under the overlapped fascia. His first operation was performed June 5, 1917, and it was therefore too early to make a final report. However, in nineteen operations done by this method he had always been able to demonstrate a strong fascia that could be overlapped and the primary results had been most satisfactory.

The Most Effective Methods of Preventing Venereal Diseases.—Dr. J. Montgomery Baldy of Philadelphia stated that legislation in the line of prohibition had

proven a failure. All methods, single and combined, used in the past had driven victims of the diseases to drug store clerks and quacks. Education of the type so far carried out had proven a failure. The "holier than thou" attitude of the community had been most disastrous. The methods of control which gave any promise whatever of success were the open treatment of the whole subject on the basis of sanitation dealing with these venereal diseases as any other class of diseases. The community must be taught that their old attitude in regard to these matters was erroneous. Hospitals must be forced to the position of repealing any rules that they might have prohibiting the admission of these cases freely to their wards. Superintendents assuming the attitude of fear of these diseases must be taught to change their attitude in these matters, or to be driven out of the business. Hospital staffs must have full liberty of admission of such patients who in their judgment needed hospital treatment. Hospitals running dispensaries must open special dispensaries for the treatment of these diseases. All advertisements in public places of a quack nature must be abolished and in their places proper types of notices of legitimate clinics at which such sufferers might apply must be substituted. This class of patients must be taught that their confidences would be kept just as secretly as would their confidence in any other class of disease, and they were perfectly safe in applying to hospitals for treatment. Hospitals must gradually provide free treatment for those suffering with these diseases who were unable to pay for the same. The question of registration by physicians of patients at public boards of health, excepting in an extremely limited way, the name of the patient being not involved, was to say the least indiscreet if results were to be obtained.

Shall We Cut and Reconstruct the Perineum for Every Primipara?—Dr. RALPH H. POMEROY of Brooklyn, N. Y., said that rending an orifice to enlarge its caliber was strictly unsurgical. He had condemned such a procedure in conditions calling for prompt and large approach to the uterine cavity through the cervix; he cut in the median line and reconstructed. The typical perineal laceration associated with spontaneous first time expulsion of a fully rotated occiput anterior position was median in principle, crudely attained in fact. A median perinectomy, preceded by thorough stretching of the sphincter ani and executed with definite technique, shortened the second stage more fortunately than pituitrin or forceps. Even though the median incision by intent or error extended through the relaxed sphincter, symmetrical repair was so simple that failure of reconstruction was not to be expected. Repair of median perinectomy might be easily done with buried and subcuticular catgut stitching so effectively as to reproduce conditions suggesting a nullipara. Such conditions, while cosmetically commendable, did not presage the conversion of the patient into a competent multipara, potentially capable of spontaneous rapid delivery without fresh wounds. He described a tentative technique for an expanding perineorrhaphy.

The Obstetrician's Responsibility for the Conservation of Infant Life.—Dr. COLLIN FOULKROD of Philadelphia stated that the investigations of the Children's Bureau of the Department of Labor of Wisconsin, of Massachusetts, of New York and of Newark had been productive of no definite program to make this question a national one, to propose laws fitted to our country and the needs. Such investigations had so far stopped short of basic causes. We must pay, as a nation, our families for producing effectives, and guarantee them the right to develop by a system of government which would be truly democratic. We must insure our mothers. We must awaken our women to their responsibility. Advanced prenatal work would in time eliminate preventable diseases and would bring the application of modern methods to non-preventable diseases. In France the pregnant woman was becoming a state care and ward. In time we should have enough hospitals in each district to scientifically care for all children born.

Why the Midwife?—Dr. J. CLIFTON EDGAR of New York City said that hospital records bore out the fact that foreign-born women, after their first confinement under the care of the midwife, subsequently turned to the maternity hospital or a physician for obstetric aid. After a short residence in this country, the foreign-born woman did not usually persist in the employment of a midwife. Her ambition was eventually to be in a financial position enabling her to employ the services of a regular practitioner. During the existence of the Bellevue Midwife School, 235 midwives had been graduated; 5,125 confinements had been conducted by the pupils, 1,755 in the school, and 3,370 in the patients' homes, with a maternal mortality of 0.7 per cent. Three cases only died in the school itself, a mortality of 0.05 per cent. Six others died after being transferred to Bellevue for operation. The 5,125 cases cared for by the midwives at the Midwife School and at the patients' homes were practically all normal labor cases, as the cases of fetal and maternal dystocia, bleeding, severe toxemia, and other abnormalities were sent to the Bellevue Obstetric Service for treatment. So far as the handling of strictly normal labor cases by the midwives went, the results had been excellent. The records indicated that little septic infection had resulted. A plan for better and safer obstetrics in the outlying rural districts must recognize two main problems: (1) The best practical care of normal cases, and (2) the detection of abnormal cases and their care. By education and supervision the midwife might be rendered reasonably safe for strictly normal labor, safe even for a minimum of sepsis, or for the prevention of ophthalmia neonatorum, but she was not safe, and no amount of education could fit the material which physicians had been brought in contact with for the early care of prenatal complications and maternal and fetal dystocia, which caused most of the infant and maternal mortality. Who should determine what was a strictly normal labor? The midwife? Never! She was incompetent to do so, and only the trained obstetrician could do so. The midwife could never stand upon her own responsibility. For safe obstetrics the obstetrician must ever perform the prenatal examination and care. He must ever be at hand for the maternal and fetal dystocia of labor and the complications of the postnatal period.

Pernicious Anemia Complicating Pregnancy.—Dr. PALMER FINDLEY of Omaha, Neb., said that while pernicious anemia was not a disease peculiar to pregnancy, it was nevertheless true that the disease occurred with unusual frequency in the course of pregnancy and the puerperium. Eichhorst in a series of 50 cases of pernicious anemia in women found 29 were associated with pregnancy and labor. Clinio, Caruso and Bertino found 0.15 per cent. pernicious anemia in all pregnancies, while Lebert and Myerrugg estimated the frequency at 0.22 per cent. We were told that pernicious anemia was more common in women than in men, but excluding all cases arising in the period of gestation the percentage of frequency was higher in men. Just what the predisposing factors were in pregnancy was not known. Prolonged lactation, frequent child bearing, the toxemias of pregnancy and unfavorable hygienic surroundings were factors to be reckoned, but were not conclusive. Neither postpartum hemorrhages nor puerperal infection tended to develop pernicious anemia if we were to judge from case records. With few exceptions, pernicious anemia rarely developed in a primipara, and was more frequently observed in a pregnancy which had been preceded by the birth of several children in rapid succession. The blood findings in the mother were characteristic. The red cells were decreased in number, even to 250,000. The blood did not show a proportionate decrease in its hemoglobin content, but there was a marked alteration in the shape, size and staining of the individual cells. Macrocytes and microcytes abounded and megaloblasts were occasionally present. Nucleated red cells did not as a rule appear until the disease was well advanced; they tended to appear in showers, and in some cases had failed to appear or at least had not been found even in the last stages of the disease. Poikilocytosis was a marked feature; fibrin and blood platelets were diminished and the leucocytes were lessened in number. In every frank case of pernicious anemia complicating pregnancy the maternal mortality was practically 100 per cent., although in exceptional cases death might be deferred for a period of weeks, months and even a year or more following

childbirth. There might be periods in which improvement might be great, but the end result was always the same. The earlier in pregnancy the disease appeared, the more rapid its course and the graver the prognosis. The management of these cases might be said to be in the interest of the mother in the early stages of the disease and of the child in the late stages of the disease. Where the disease was well advanced, the child living and approaching the period of viability, pregnancy should be allowed to proceed to term, if possible, in the hope of delivering a healthy child. The case of the mother was hopeless and no good could come from sacrificing the child by the interruption of pregnancy. Two cases of pernicious anemia complicating pregnancy were reported, with one death.

Treatment of Puerperal Blood Stream Infection by Means of Arsenobenzol, with Report of Cases.—Drs. H. A. MILLER and S. A. CHALFANT of Pittsburgh said that no form of intravenous medication up to the present time had been entirely satisfactory, although many had been tried. Puerperal bacteriemia had always been a very serious condition with a high mortality. The treatment as used in these cases was followed up by experimental work by Allison. He found that arsenobenzol, together with similar preparations, could be given frequently in large doses without injury to the animals, that the mortality was less in treated than in untreated animals and that the injection of arsenobenzol would usually rid the blood stream of streptococci in 24 hours. He also showed that there was a fall in the leukocyte count before the blood culture again became positive. The authors had treated eleven cases of puerperal infection by means of arsenobenzol given intravenously usually in 6 gm. doses as frequently as three or four day intervals, giving from one to four doses. There were no toxic effects other than a mild albuminuria. Seven patients had a streptococcus in the blood stream with two deaths, two a Gram negative bacillus, with no deaths, and two had a negative blood culture, but were both clinically bacteriemias and both died. Two patients had intrauterine irrigations at two hour intervals with Dakin's solution, of which one recovered and one died. In the fatal case autopsy showed the uterus free from infection. Death was due to multiple abscesses of both kidneys. The following were the authors' conclusions: "(1) With the use of intravenous injections of arsenobenzol we have been able in every instance to rid the blood stream of its invading organism. (2) All varieties of organisms so far encountered seem to be equally influenced. (3) Cultures from localized abscesses are usually identical with cultures from the blood stream. Cultures from the uterus, although this organism predominates, are rarely pure cultures. (4) Reinfections from focal infections may and do occur, but are as readily influenced by arsenobenzol as the original infections. (5) The leukocyte count is usually low in comparison with the temperature and pulse. After arsenobenzol has been given there is a marked increase in the count. If, after this time, there is a decided decrease in the leukocytes with a corresponding improvement in the patient, including the pulse and temperature, it is very possible that the patient has reinfected herself, and arsenobenzol should be given without waiting for confirmation of this culture report. (6) The blood stream is usually found to be sterile in 24 hours, always in 48 hours, except in one case where but 4 gm. of arsenobenzol was given. (7) Rabbit experiments made by Dr. C. S. Allison would indicate that a dose of 6 mgs. is necessary to secure prompt results. (8) In suspected blood stream infections arsenobenzol may be given immediately after a culture has been taken in order to avoid the delay incident to waiting for a laboratory report."

Coincident Pathological Conditions Associated with 1500 Consecutive Myomata Uteri.—Dr. LEROY BROUN of New York City said that he had reviewed all of the myomata operated on at the Woman's Hospital during the past eight years, ending with September, 1917. There were 1,500 such cases. All of these had some form of hysterectomy or myomectomy. As a result of the operations, 28 patients died. Of these, 7 died from embolus, chiefly between the eighth and twentieth day. Seven died from peritonitis, and the remainder from various causes. The percentage rate of 1.86 could be taken as a fair estimate of the mortality of operations for this condition, since it represented the results of the combined operative work of a large attending and junior attending staff, together with that of a liberal corps of surgeons, who were given the privilege of sending their patients to the private rooms of the hospital. This compared favorably with 1.73 per cent. reported by Deaver in 759 cases covering a period of 11 years and with 1.75 per cent. reported by Frank in 400 cases operated on by Brettauer and himself. Associated with the total number of cases (1,500) 66 malignant conditions were found, 29 of which could be unquestionably determined before operation. It was doubtful whether all of the 7 cases of sarcoma could have been determined, and it was certain that the nature of the remaining 21 cases of malignancy, ovarian carcinoma, 4, and papillomatous cyst, 17, could not have been previously diagnosed before opening the abdomen. Of the ovarian pathology associated, 58 cases occurred. The previous recognition of any of these conditions before operation, excluding the four instances of abscess of the ovary, would depend entirely on the size and character of the myoma present, also on the size of the pathological ovarian conditions associated. There were 265 cases of associated tubal disease, the majority of which would have required at some time surgical interference. To what extent the circulatory disturbance as a result of the presence of the tumor was the cause of the predominating presence of salpingitis could not be stated. No tube was, however, reported as the seat of inflammatory changes, unless positive pathological examination and evidence showed such a condition. A large number of uterine appendages were removed in connection with hysterectomies in patients about the menopause, in whom only minor pathological changes were found. None of these were included among the 150 cases of salpingitis cited. One hundred and sixty-seven chronic or subacute appendices were found. There wase 9 instances of associated extrauterine pregnancy and 51 of normal pregnancy. Three hundred and fifty-five cases, 23.7 per cent. of the 1,500 consecutive myomatas operated on, contraindicated the use of radium and the *x*-ray. He was convinced from a review of these cases that the symptoms, on account of which the majority of patients entered the hospital, were due in the greatest measure to conditions outside of the uterus and not to the presence of the tumor itself, unless it was from hemorrhage.

Final Results of X-Ray Treament of Fibroids.—Dr. JOSEPH BRETTAUER of New York City, in concluding his paper, formulated his views on the *x*-ray treatment of fibroids as follows: "(1) At an age below 45 the *x*-ray treatment for fibroids should not be the choice, but should be employed only when operative measures are not available or are refused. (2) Between the ages of 45 and 55, *x*-ray treatment should be the method of choice and no patient should be deprived of the right to undergo it. With an open cervix and a distinct diagnoses of the submucous development of a fibroid, operative measures promise better results. Patients with relaxation and laceration of the genital tract should be excepted. These cause no symptoms while the uterus is large and above the pelvis, but when as a result of the treatment the uterus becomes smaller and sinks down into the pelvis, serious inconvenience is caused and operative interference becomes necessary for its relief. (3) Uterine hemorrhages due to fibroids in women beyond the age of 55 should raise suspicion of sarcomatous degeneration and operative measures are preferable to any other form of treatment."

Two Hundred and Ten Fibroid Tumors Treated by Radium.—Dr. HOWARD KELLY of Baltimore said that the only effective method of treating fibroid tumors of the uterus up to the present time had been the surgical, developed with such care through two generations, until the operation had become in skilled hands one of the safest of our major procedures. The author had operated in this way upon 2,000 women, but felt now that the radium treatment, which was without danger and which was found effective in 93 per cent. of the cases, should be preferred to the operation, which was, after all, a major operation of mutilating character offering considerable risk to life and health. He stated his thesis with regard to the accomplishments of radium in this class of cases as follows: 1. Control of hemorrhage and checking of menstruation. 2. The shrinkage

of the tumors. 3. In many instances the disappearance of the tumors. 4. In some cases, even after two years, the return of menstruation either normal or scanty. There had been no mortality associated with the treatment of 210 consecutive cases. Between the dates of March 23, 1913, and January 8, 1918, 210 cases of uterine fibroids were treated with radium by the author and by Dr. Curtis F. Burnam, and 45 cases were operated on either because there was some contraindication to the use of radium or because operation was preferred. In 28 of these 210 cases the data were insufficient; 6 did not complete treatment, although 4 of these were markedly benefited; 7 had been lost sight of; 2 died of causes unconnected with the treatment; 13 were too early for results to be reported with certainty. There were, therefore, 182 cases in which the results were known. In 171, or all but 11 cases, radium alone was sufficient to relieve the patient. In these 171 cases (93 per cent.) the tumor was either gone or markedly diminished, or the patient was symptomatically well. In 5 of the 11 cases some complicating condition was present (ovarian cyst, gallstones, calcified uterus); in 2 cases operation was preferred to further treatment; in 3 cases operation was found not to have been necessary, as the tumor had decreased under treatment; one case proved resistant to prolonged treatment. Nine of the 11 cases were operated on. The fact should be emphasized that if radium failed, the operation has simply been postponed without detriment to the patient. The technique of the treatment included a preliminary curettage both to rule out malignancy and to remove any small polypi which might be found to exist. The average inside application was for 3 hours with 500 microcuries of emanation. A small glass bulb was placed in the end of a metal tube, sufficiently thick to screen off all but the gamma rays. This tube was screwed onto a uterine sound and was then covered by a rubber cot. The cervix was dilated and the sound introduced to the top of the uterine cavity. The applicator was gradually withdrawn, not being allowed to remain longer than one-half hour on each spot. In the external treatments to shorten the time, 4 to 5 grams of radium were being used and the entire treatment could be given in from 5 to 6 hours. In any one case the treatments, internal and external, could be given individually or combined in any desired method. At least 7 weeks should be allowed to elapse before a second treatment was given, and it should not be given if an amenorrhea was already obtained. Usually the second should be an external one. Some tumors reduced rapidly; others slowly over a year or more. Menopausal symptoms were usually not severe. In 50 per cent. of the cases no menopausal symptoms were complained of; in slightly more than 25 per cent. they were moderate and in slightly less than 25 per cent. they were marked.

Consideration of Some of the Technical Problems Connected with the Use of Radium by the Gynecologist.—Dr. Curtis F. Burnam of Baltimore stated that the basic principle underlying all radium treatment was that pathological tissues were in general more sensitive to radiation than normal tissues, and that consequently it was possible with appropriate dosage to destroy the former and leave the latter intact. The gamma rays of radium, which alone could be used for therapeutic purposes, could not be focused and consequently were dispersed in the form of a sphere. This led to their rapid dilution inversely with the square of the distance. In addition there was an absorption of about 8 per cent. per cm. in tissue. The absorption in tissue could not be helped. It was, however, possible to minimize the dispersion factor by placing the source of radiation away from the surface and consequently increasing the radium as well as the time of exposure. If the radium was placed 2 mm. from the surface, at 1 cm. below the surface, only 2.5 per cent. of the surface application was still present, and at 5 cm. only 0.107 per cent. remained. But if the radium was placed 12 cm. above the surface, at 1 cm. below the surface 78 per cent. of the surface radiation was still intact; at 5 cm. 35.8 per cent., and at 9 cm. a little less than 20 per cent. Radiosensibility of tissue was extremely difficult to determine. Individuals varied immensely so far as normal tissues were concerned. Variations of tumors of the same type were even more marked. The same tumor varied at different stages of its development. The single dose method was very valuable in giving us standards to work by, but the broken dose method at week intervals permitted of giving nearly twice the dose within six weeks, the time necessary to elapse between massive treatments. At a distance of 2½ cm. from the skin a gram of radium on an applicator 2½ cm. square filtered through 2 mm. of lead would lead to an erythema in 2 hours and would cause a marked retrogression or cure of an epithelioma. One one-thousandth of this dose might be effectual in destroying large masses of lymphosarcoma or of splenomyelogenous spleen tissue. Three or four times the dose, however, had to be given to destroy normal skin. Ovarian tissue was roughly 10 times as easily injured as normal skin; the vaginal wall would tolerate four or five times the skin dose; the rectal mucosa as much as the skin; the mucous membrane of the bladder certainly twice as much. The vaginal and cervical cancers were fully as susceptible to treatment as skin cancers, perhaps more so. The adenocarcinomas of the rectum as well as of the body of the uterus were decidedly more susceptible than epithelioma. Uterine fibroid tissue was tremendously more susceptible than normal skin. The dosages given were for massive radiation with at least six weeks' interval between treatments. They could not, as a rule, be repeated then without leading to more or less destructive effects on surrounding normal tissue. Effectual treatment could only be secured by careful preliminary determination of the distances of all parts of the growth from the portals. Cross fire radiation should be employed and normal tissues protected by pushing the parts aside wherever possible and by metal screens. For radiation within the cervix, uterine cavity, and rectum, the radium emanation was inclosed in glass tubes, these in metal tubes, and these in rubber tubes, securing a pure gamma radiation. The small growths of the bladder were best treated by direct application through a cystoscope. Extensive infiltrating bladder growths and some rectal cancers were best treated from without the body. A number of illustrative cases of cervical and vaginal cancers were discussed in detail. Appropriate treatments for each were suggested. The injuries likely to result from over-radiation, such as fistulæ and rectal ulcers, were described, as were also the most effectual methods of guarding against them.

Clinical Data on Chorioepithelioma, with Report of Cases.—Dr. Hiram N. Vineberg of New York City said that chorioepithelioma occurred in two types, benign and malignant, but as yet there were no recognizable histological differences between the two varieties. An endeavor should be made to make a diagnosis on clinical data, inasmuch as a curettage was attended with the risk of causing rapid and extensive metastases. Furthermore, a microscopic examination of the curetted material was not always decisive, and might even be misleading. For the present, not knowing the cause, we could have no means of prevention. But, as a possible safeguard, placental residue, when present, should be promptly removed, and in every case of hydatid molar pregnancy, an anterior hysterotomy should be done for the double purpose of removing all the vesicles and exploring the entire inner wall of the uterus for any suspicious nodules or extra thinning of the wall at any one point. Once the diagnosis had been made, panhysterectomy was indicated, as we had no means of differentiating between the so-called benign and the highly malignant cases.

Cancer of the Cervix Complicating Triplet Pregnancy.—Dr. Benjamin P. Watson of Toronto reported the following case: Patient, aged 30 years, 5 para, pregnant. On examination a large cauliflower carcinoma was found growing from the anterior lip of the vaginal portion of the cervix. The abdomen was opened, the uterus incised, and three five months' fetuses removed, and then three separate placentas connected by membrane. A Wertheim operation was then proceeded with. The patient made a good recovery. He reviewed the histories of other cases of cancer of the cervix complicating pregnancy.

Description of Goffe's Gastrocolonopexy Operation.—Dr. J. Riddle Goffe of New York City stated that from his experience he had gradually evolved the method which he now employed as follows: This description embraced the complete operation in which both stomach

and colon were involved in extreme ptosis and adhesions. A longitudinal or transverse incision was made below the umbilicus. Through this adhesions were severed, the organs were set free, the appendix was removed, the caput, if overdistended, plicated, the uterus, which was frequently found displaced, restored to normal position and supported there, and if necessary the appendages were dealt with as indicated. The incision was closed. A longitudinal incision was then made above the umbilicus through which the upper abdominal cavity was thoroughly explored with the hand, noting the condition of the liver, its ligaments, the gall bladder, and ducts especially. Any pathologic conditions were dealt with according to indications, new incisions having been made or the original one enlarged, if necessary. The stomach was then delivered through the wound, inspected and palpated for ulcers and pyloric irregularities. If dilated, the anterior wall was depressed with a sound along the middle line and over this the stomach wall was plicated in a double row of linen sutures. In a line just above or below this, and midway between the extremities of the stomach, two, three or more linen sutures were threaded along in the stomach wall, including the peritoneal and muscular coats, each one being buried for one-half to three-fourths of an inch, the two ends left long and protruding from the wound. They were wrapped in sterile gauze. The transverse colon was then delivered through the wound, the omentum ligated along the border of the gut and cut away. The long sutures were threaded singly in a Peasley needle and passed successively through the abdominal wall into the interior of the abdomen and brought out in the bottom of the skin incisions previously described. First, the stomach sutures were passed, emerging in the middle incision, the stomach restored to normal position, the sutures drawn taut, tied and cut short. The three pairs of sutures in the colon were successively passed in the same way, each pair in the three designated loci of the colon, being directed to the incision in its corresponding location. All the sutures were drawn taut to straighten out the intestine and make intimate contact between it and the parietal peritoneum, and were then tied external to the deep fascia in the bottom of the incision and cut short. The three incisions were then closed with a subcuticular catgut suture and sealed with sterile collodion. It would be observed that the fixation sutures of the stomach and transverse colon were brought out through the same incision. When both organs were to be attached the fascia in the bottom of the wound was laid bare for half an inch above and below the mid line of the incision and the respective sutures passed at the extreme limits of the denuded spaces, the stomach sutured above and the colon sutured below. The sutures composing the pairs were threaded along in the same line and about one-quarter of an inch apart. He had deemed it advisable in some cases to link the sutures together, thus converting them into a figure of 8 or chain suture. This distributed and equalized the tension over a broader area and diminished the tendency to contract. The abdominal wound was closed in the usual three layer method. Adhesive plaster and abdominal binder were applied rather tightly, and the foot of the bed kept elevated from 6 to 18 inches according to the tolerance of the patient.

The Graduate Degree in Obstetrics and Gynecology.—Dr. JENNINGS C. LITZENBERT of Minneapolis said that the Minnesota plan for graduate work in the medical specialties was new, but new only in its application to medicine. The plan simply applied the principles governing university graduate work in any other branch of advanced learning to the medical branches and placed them not only under the same principles, but actually in the graduate school of the university. The requirements for entry were a college degree, a medical degree, and a thorough reading knowledge of French and German, and an internship of at least one year. The course extended over three years of work with a major and a minor, the same as candidates for other advanced degrees, and examinations were by graduate faculty. A thesis, which must be an original contribution to science, was required and must be defended. This led to the degree of Doctor of Philosophy in Obstetrics and Gynecology. A two years' course might lead to Master of Science. Withal it was a plan to raise to a high level the training of specialists.

The Use of Dakin's Solution in Suppurative Conditions Within the Peritoneal Cavity.—Dr. RALEIGH R. HUGGINS of Pittsburgh read this paper, of which the following were the conclusions: "(1) When Dakin solution is brought in proper contact with an infected surface it will destroy pus; if this does not happen, it is because there is some focus not reached by the solution or because of imperfect technique. (2) As a result of its use there is rapid return of strength, and the postoperative course is more comfortable and with less danger of secondary complications. (3) Any offensive smelling discharge is destroyed almost immediately. (4) It is contraindicated in the presence of an intestinal fistula. (5) That it may delay the final healing by interfering with the normal granulating process in some instances, may be true. Further observation is necessary to determine this question."

A Study of Dystrophy Adiposa Genitalias in Women.—Dr. EDWARD A. SCHUMANN of Philadelphia read this paper, of which the following were the conclusions: "The syndrome resulting from the effects of deficient pituitary secretion upon the female sexual system may properly be divided into three clinical groups, according to the sex epoch affected. The terms 'amenorrhea of obesity' and 'lactation atrophy' or superinvolution of the uterus are no longer correct since it seems reasonably well proven that both these conditions are but phases of a primary hypo-pituitarism. Definite regressin of the reproductive tract may follow deficient pituitary secretion in parous women of mature age, and may and frequently does give rise to erroneous diagnosis of pregnancy. Treatment for all groups consists in general measures and the empirical use of glandular extracts, the systolic blood pressure being a fair index of the particular gland substances to be employed; low pressure indicating pituitrin; high pressure, thyroid. The prognosis is guarded in all cases, as to recovery, but is favorable in direct ratio with the age of the patient."

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

WAR WOUNDS OF THE LUNG. By PIERRE DUVAL. 99 pages. Illustrated. Price, $2.25. Published by William Wood & Company, New York.

THE NORMAL AND PATHOLOGICAL HISTOLOGY OF THE MOUTH. By ARTHUR HOPEWELL-SMITH. Volume II. 477 pages. Illustrated. Price, $4.50. Published by P. Blakiston's Son & Company, Philadelphia.

PRINCIPLES AND PRACTICE OF FILLING TEETH By C. N. JOHNSON, M.A., L.D.S., D.D.S. Fourth Edition. 286 pages. Illustrated. Price, $3.00. Published by P. Blakiston's Son & Company, Philadelphia

CONCERNING SOME HEADACHES AND EYE DISORDERS OF NASAL ORIGIN. By GREENFIELD SLUDER, M.D. 272 pages. Illustrated. Published by C. V. Mosby Company, St. Louis.

ESSENTIALS OF DIETETICS. A Textbook for Nurses. By Maude A. Perry, B.S. 159 pages. Published by C. V. Mosby Company. St. Louis.

THE WASSERMANN TEST. By CHARLES CRAIG, A.M. 239 pages. Illustrated. Published by C. V. Mosby Company, St. Louis.

MILITARY SURGERY OF THE ZONE OF THE ADVANCE. By GEORGE DE TARNOWSKY, M.D., F.A.C.S. 330 pages. Medical War Manual No. 7. Illustrated. Price, $1.50. Published by Lea & Febiger, Philadelphia and New York.

SURGICAL APPLIED ANATOMY. By Sir FREDERICK TREVES, F.R.C.S. 702 pages. Illustrated. Price, $3.00. Published by Lea & Febiger, Philadelphia and New York.

SOCIAL RESPONSIBILITIES IN THE REHABILITATION OF DISABLED SOLDIERS AND SAILORS.

By DOUGLAS C. McMURTRIE,

NEW YORK.

DIRECTOR RED CROSS INSTITUTE FOR CRIPPLED AND DISABLED MEN; PRESIDENT, FEDERATION OF ASSOCIATIONS FOR CRIPPLES; EDITOR, "AMERICAN JOURNAL OF CARE FOR CRIPPLES."

THERE are distinct social responsibilities in the rehabilitation for civilian life of disabled soldiers and sailors. In the restoration of the man to self-support, although the medical treatment be thorough and efficient, though reeducational provision be excellent, and though the will and spirit of the men under training may be of the best, yet the complete success of the program will depend upon whether the attitude of the public acts as a help or a hindrance—upon whether the influence on the individual ex-soldier of his family, his employer, and the community at large is constructive or demoralizing.

What, then, is the public duty toward the disabled soldier? For it is certain that the requirements need only to be understood to be fulfilled.

The first responsibility on the part of the family of the injured man is to learn the meaning of disability, and see the hopeful rather than the depressing aspect. Just recently in the suburb of a large Pennsylvania city a woman in a swoon was found on the steps of the local postoffice. She had just opened a letter from her son at the front which told of a gunshot injury necessitating amputation of his left arm below the elbow. Immediately there rose before her eyes the terrifying prospect of a life of idleness and possible pauperism. One can imagine what her next letter would be like: saying she knows what the amputation means and sympathizes most tenderly on account of what must be faced in the future. If it were only a leg it would not be so bad, for then he might be able to take care of himself and get some kind of a job, but with an arm off, he could not expect to do that. But she and father have saved up some, and with uncle's help they will take care of him till the end of his days. Picture the influence of this message in comparison with another which might be sent in the light of a fuller understanding of what is possible: "I have just heard of your arm amputation and sympathize most lovingly in your loss. But I know you will not lose your courage, even at this sacrifice for your country. Even now, the national authorities are making plans to make up so far as possible for such losses, as you doubtless already well know. One-armed men can be trained for skilled jobs, especially men with native ability such as yours, and the training is already under way in the city near us. The employers also here are becoming tremendously interested in the subject, and are finding jobs specially suited to men who have lost arms or legs and have promised these jobs to the fellows who return from the front disabled. And you can count on our standing behind you at every step and helping in every way we can. This is really a fine future to look ahead to for if you make good here at home with your handicap of honor, you and we will have true reason to be proud. And of course you will succeed if you go at this obstacle with the same spirit and nerve as have gone toward your work in the army. Your mother will look forward to your return home wearing the uniform of Uncle Sam and flying the colors of a soldier who can't be beaten."

It is greatly to be desired that the families of men going to the front should know of the possibilities of reeducation and reemployment and of the provision being made for the disabled, for it would mitigate not only a great deal of mental suffering over actual injuries but over prospective disabilities as well. It is well known that the greatest fear regarding service in the trenches is not the loss of life but the prospect of returning crippled. As one writer has well put it: "To die for one's country: if one could only be sure of dying!"

In coming down in the elevator of a large New York department store recently, the day following the publication in its pictorial section by a great daily newspaper of the photograph of the first American amputation cases in France, the following remark was overheard: "Did you see those horrible pictures in the paper yesterday? I do hope that Jack will not come home that way: I would rather he be killed." Yet the picture showed only foot amputations and to one familiar with cripples and their potential accomplishments such a disability seems a real inconvenience but nothing more. The woman quoted was suffering unduly in her apprehension.

It is not here intended to minimize the seriousness of the total disabilities but these occur in but one case in a hundred thousand. The point is that many injuries that might be regarded as terrible under unintelligent handling in the past no longer remain so.

The second responsibility of the family is to understand the importance to the disabled soldier of the proffered training for self-support, and to encourage him in every possible way to undertake

it. The family must do more than avoid opposition to the soldier's plan for reeducation; they must do more than give it lukewarm assent—they must get behind it with every influence at their command.

Failure to have the family understand and support the program for the future of the disabled man may have disastrous results. In France the mother occupies an unusual place of authority in the family economy. A son may grow up to be twenty, thirty, or forty years old, but mother is still a chief to whom obedience is unquestionably paid. In dealing with the *poilu*, therefore, one must count in his maternal parent as well. At one French center of hospital care and reeducation it was found that, as a man would approach the point of his medical recovery and approach the time of entry on vocational training, his mother was liable to descend upon the hospital office, beat her umbrella on the table, inquire why they were keeping her son so long away from home, and demand his immediate discharge in order that she might take him away "to care for the poor crippled boy for the rest of his life." In vain were explanations and arguments regarding the efficacy of further treatment and training. She had come there determined to take her son away, and the scene would continue until her end was accomplished. And in most instances there was nothing to do but accede to the mother's demand.

But a better way was found of dealing with the families of men deemed likely to benefit by reeducation. Under this procedure when the soldier was nearing the end of his hospital care the director of the institution would summon the mother to come in and advise regarding her son's future. She would then be addressed something in this wise: "Your son's medical treatment will, in another week or two, be practically complete, and we thought you might like to know so that, if you desired, you could make plans to take him home. But you know he is permanently disabled and will not be able to go back to his old job of telegraph lineman. We know that you expect to care for him, but he will outlive you, and later, since the government pension is small indeed, he will be reduced to a miserable situation. You remember the cripples from the War of 1870, how they begged or sold trinkets about the streets—and you would not want your son to be in that fix. Luckily, however, he will not have to be for we have something else to suggest. Across the street is a school where the men are taught various skilled trades. If your son cares to stay for five or six months, and you approve, we will teach him to be a telegrapher and he can go back to his home town and get a good job with the government telegraphs. As a skilled worker still he will be doubly respected in the community, he will be a burden on no one, his future will be assured, and you will be very, very proud of him. What do you think wise under the circumstances?"

The whole situation is changed. Mother greets her boy with: "Son, have you heard what they are going to do for you?" And as the son has already been talked to regarding the program, the joint decision is assured.

This illustrates the difference between a family for or a family against the proposal of reeducation.

The third duty of the family is to stand behind the man during his course of training and try in every way to encourage rather than dishearten him. Letters from home which recite all the troubles of life and none of the joys will not help the enterprise. The family reaction should rather be: "Stick to it; we are getting along all right and want to see you finish the job up right, now that you are at it." In other words it is necessary to maintain the morale of the family in the same way as when the man is at the front. This is largely contributed to by home visitors such as those of the Canadian Patriotic Fund or the American Red Cross.

The fourth family responsibility toward the disabled man is to make the home influence as sensible and as truly helpful as possible after his return from hospital or school. The first and very natural impulse when son or husband comes home crippled or blind is to pet him and wait on him hand and foot. Yet the best interests of the family as well as of the man himself demand his being encouraged to do for himself everything he can, with the aim of stimulating that self-dependence which has been the object of his whole course of training. Within the limits imposed by affection the family should endeavor to carry along the spirit of that training.

In the readjustment of the crippled soldier to civilian life the employer has a very definite responsibility. But this duty is not entirely obvious. It is, on the contrary, almost diametrically opposite to what one might superficially infer it to be. The duty is not to "take care of," from patriotic motives, a given number of disabled men, finding for them any odd jobs which are available, and putting the ex-soldiers in them without much regard to whether they can earn the wages paid or not.

Yet this method is all too common. A local committee of employers will deliberate about as follows: "Here are a dozen crippled soldiers for whom we must find jobs. Jones, you have a large factory: you should be able to take care of six of them. Brown, can you not find places for four of them in your warehouse? And Smith, you ought to place at least a couple in your store."

Such a procedure cannot have other than pernicious results. In the first years of war the spirit of patriotism runs high, but experience has shown that men placed on this basis alone find themselves out of a job after the war has been over several years, or, in fact, after it has been in progress for a considerable period of time.

A second weakness in this method is that a man who is patronized by giving him a charity job comes to expect as a right such semi-gratuitous support. Such a situation breaks down rather than builds up character, and makes the man progressively a weaker rather than a stronger member of the community.

The third difficulty is that such a system does not take into account the man's future. Casual placement means employment either in a makeshift job as watchman or elevator operator such as we should certainly not offer our disabled men except as a last resort—or in a job beyond the man, one in which, on the cold-blooded considerations of product and wages, he cannot hold his own. Jobs of the first type have for the worker a future of monotony and discouragement. Jobs of the second

type are frequently disastrous, for in them a man, instead of becoming steadily more competent and building up confidence in himself, stands still as regards improvement and loses confidence every day. When he is dropped or goes to some other employment, the job will have had for him no permanent benefit.

Twelve men sent to twelve jobs may all be seriously misplaced, while the same twelve placed with thought and wisdom and differently assigned to the same twelve jobs may be ideally located. If normal workers require expert and careful placement, crippled candidates for employment require it even more.

The positive desideratum is to find for the disabled man a constructive job which he can hold on the basis of competence alone. In such a job he can be self-respecting, be happy, and look forward to a future. This is a duty not so easy of execution as telling a superintendent to take care of four men, but there is infinitely more satisfaction to the employer in the results, and infinitely greater advantage to the employee. And it is entirely practical, even in dealing with seriously disabled men.

Thousands of cripples are now holding important jobs in the industrial world. But they are men of exceptional character and initiative and have, in general, made their way in spite of employers rather than because of them. Too many employers are ready to give the cripple alms, but not willing to expend the thought necessary to place him in a suitable job. This attitude has helped to make many cripples dependent. With new responsibilities to the disabled soldier, the point of view must certainly be changed. What some cripples have done, other cripples can do—if only given a chance.

This, then, constitutes the charge of patriotic duty upon the employer:

To study the jobs under his jurisdiction to determine what ones might be satisfactorily held by cripples. To give the cripples preference for these jobs. To consider thoughtfully the applications of disabled men for employment, bearing in mind the importance of utilizing to as great an extent as possible labor which would otherwise be unproductive. To do the returned soldier the honor of offering him real employment, rather than proffering him the ignominy of a charity job.

The responsibility to the disabled soldier on the part of the community at large is much more complex, since the contact exists at a multitude of points and is at none highly intimate. The first reaction of the public to the returning man is hero-worship of the most empty type—described coldly it usually consists in making a fool of the man and entertaining him in inappropriate and hurtful ways.

One form of this is society lionization—and for but the proverbial six days indeed. To a large Canadian city there returned a disabled soldier after two years' absence at the front. His wife and children had been looking forward expectantly to having him with them, but after his arrival saw but little of the head of the house. As a national holiday was approaching they were counting on his accompanying them to the park, and had exacted a tentative promise that he would do so. But as the morning arrived and mother was dressing the children to start, father made no move to get ready. Almost tearfully mother asked if he was not going with them. "Oh, no," he answered, "I am going for an automobile ride this morning and this afternoon to a sing-song at the—(naming a fashionable hotel)." Thus was the community showing kindness to the returned soldier and helping to put him back on his feet.

The man on the street thinks the greatest service to the disabled fighter, particularly when he is discharged from the army and no longer under the partial protection of the khaki, to consist in buying him at the corner saloon as many drinks as he can hold. From one small American city a social worker reported inability to distinguish as to whether certain discharged men were suffering from shell shock or intoxication, so hearty was the hospitality of the citizens. Such "kindness" requires no comment. Fortunately the war-time measure regarding the liquor trade will soon make this impossible, and will guard the ex-soldier from one pitfall. It may be noted in passing that this will be a boon to the returned men in more ways than one. In Canada at a time when most of the provinces had prohibition and one or two others limited license, the placement of disabled men in employment was many times simpler in the dry territory than the wet. In the latter many men lost jobs again and again by reason of intoxication, not only injuring themselves but weakening the standing of their fellows as well in the eyes of the employers.

Finally there is the great general public prejudice against the disabled, the incredulity as to possible usefulness, the apparent will to pauperize, and the reluctance through usual channels of opportunity to give the handicapped man a chance. Successful crippled and blind men unanimously testify that the handicap of public opinion is a greater obstacle than amputation of limb or loss of sight. And this unenlightened attitude is manifest in every social relation of the disabled—with family, with employer, with the community as a whole.

It becomes clear, therefore, that a necessary feature of any program for restoring the disabled soldier to self-respect and self-support is a campaign of public education to convert the general attitude toward the crippled and handicapped.

This need was recognized most clearly among our enemies by Germany and among our allies by Canada. There was signal failure to appreciate the value of public education in France, Great Britain, and Italy. There is no need of it yet in Belgium as all the disabled men are retained in the army and provided not only with training but with employment as well, and there is no family problem as the men cannot return home.

Within a few months of the opening of the war, the secretary of the German national federation for the aid of cripples made a tour of the leading cities of the Fatherland speaking to meetings of public officials, social workers, and the like, with the aim of disseminating intelligence regarding modern principles and methods of dealing with the disabled. The same authority prepared several pamphlets of popular character which were distributed in editions of over a hundred thousand. There was in existence at the outbreak of the war an excellent monthly journal on work for cripples, and this

devoted its columns to the subject of provision for the war disabled. Some other special publications in the same field immediately sprang up. One of these has the interesting title of "From War to Industry."

There has been issued under the title of "The Will Prevails" a volume of biographies of cripples who have overcome their handicaps—from Tamburlaine down to men disabled in the present war. The book is intended for circulation in hospitals and for general reading. Exhibitions illustrating in a practical way the possibilities of the war cripple constitute another vehicle of public education, and have been held in the leading centers of the empire. Moving pictures and lantern slides are also being utilized for propaganda to stimulate interest on the part of the people and to arouse ambition and courage on the part of the disabled themselves.

In Canada a real and very intelligent effort has been made to acquaint the people with the aim and practice of reeducation. A well-known poster, printed in red and black, entitled "What Every Disabled Soldier Should Know," is widely in evidence throughout the Dominion. It is really addressed as much to the public as to the returned soldier. The text of the poster is as follows:

That there is no such word as "impossible" in his dictionary.
That his natural ambition to earn a good living can be fulfilled.
That he can either get rid of his disability or acquire a new ability to offset it.
That the whole object of doctors, nurses, and instructors is to help him in doing that very thing.
That he must help them to help him.
That he will have to have the most careful and effectual treatment known to science.
That interesting and useful occupations form a most valuable part of the treatment in the convalescent homes and sanatoria.
That if he can not carry out his first duty by rejoining his comrades at the front, and if there is no light duty for him with the Canadian forces overseas, he is taken home to Canada, as soon as his condition and the shipping facilities make this possible.
That his strength and earning capacity will be restored there to the highest degree possible, through the Invalided Soldiers' Commission.
That if he requires an artificial limb or kindred appliance it will be supplied free.
That every man disabled by service will receive a pension or gratuity in proportion to his disability.
That if his disability prevents him from returning to his old work he will receive free training for a new occupation.
That full consideration is given to his own capacity and desires when a new occupation has to be chosen.
That his own will-power and determination will enable him to succeed, both in the training and in the occupation afterward.
That his maintenance and that of his family will be paid for during the training he may receive after discharge, and for a month longer.
That neither his treatment nor his training will cost him a cent.
That his home Province has a special commission to assist him in finding employment on discharge.
That hundreds of towns and villages have committees, associations, and clubs, to welcome him on arrival, and to help in securing a position for him.
That the Dominion and provincial Governments, the municipal authorities, and all sorts of employers, give the returned soldier preference in filling vacant positions.
That the returned soldier wishing to take up land and farm it will be helped to do so, under Federal and other settlement schemes.
That the Invalided Soldiers' Commission exists to carry out his restoration and training in Canada.
That the Board of Pension Commissioners exists to distribute the pensions provided by his country for him and his dependents.
That the Invalided Soldiers' Commission and the Board of Pension Commissioners are in the position of trustees, appointed for his benefit, and representing the whole people of Canada.
That, therefore, he should write direct to the Commission or the Board if he needs advice or help.
Canadians are unanimously resolved that every returned soldier shall have a full opportunity to succeed. When that opportunity is put within his reach, his success will depend on his own good sense in seizing and using it.

Another poster of pictorial character shows a one-armed man fitted with an artificial appliance at work on a drill press.

The daily press has been supplied with material descriptive of the success of men who have completed training and made good. Some stories have carried with them a little preachment as to the sound attitude toward the disabled soldiers. One concludes with this statement: "Every man doing steady work suited to his capacity is a gain to himself and his country. Every man left idle, or performing some trifling task beneath his capacity, or trying to do work he is unfit for, is wasted. And Canada cannot afford to waste a man."

A remarkable moving picture film in ten reels has been prepared by the government authorities to illustrate the progress of the disabled soldier after his return from overseas. It shows reception at the debarkation depot, transportation in a hospital train, various forms of treatment at military hospitals, recreation, vocational training, and, finally, reemployment in industry. The message of the series of reels is "that injury does not mean pauperism: that every man is given a chance to make good." Where the man does not try to help himself, however, there is shown the opposite eventuality of vagrancy. The film is for exhibition in Canadian military hospitals in England, and for showing to the public of the Dominion.

In the United States there has been as keen if not a keener realization of the fundamental importance of public education to the cause of the disabled as in any other country, and as might probably be expected actual work on such a campaign began at an early date. The Surgeon General of the Army issued in October, 1917, a clear statement of the modern policy and spirit of dealing with the disabled soldier, under the title of "The Passing of the Cripple." Later the same office made an excellent contribution to the cause in the preparation of moving picture films of five successful American cripples who were seriously handicapped, yet had overcome their obstacles. This series of reels was entitled "The Way Out," and was intended for showing to the general public and in hospitals overseas to men who have just met with disabling injury. The set is one item in a "cheer-up campaign," another projected feature of which is the issue of a volume of biographies of disabled Americans who have beaten their handicaps. Still another factor in this work is the issue by the Surgeon General, in cooperation with the American Red Cross, of an inspirational magazine, by name "Carry On," which aims to convey to members of the army medical corps, to army nurses, to Red

Cross home service workers, and to the public at large some conception of the new spirit in dealing with wounds, of more kinds than one, which are sustained at the front. This magazine has already a monthly circulation of over a hundred thousand.

An unofficial campaign in the interest of the disabled was early initiated by the Red Cross Institute for Crippled and Disabled Men. One of the most familiar items in this campaign was a small folder of which over seven million copies were distributed, largely through the courtesy of telephone, gas, electric, and other public service corporations. It was titled, "Your Duty to the War Cripple" and its text—which epitomizes the gospel preached in the campaign—read as follows:

When the crippled soldier returns from the front, the government will provide for him, in addition to medical care, special training for self-support.

But whether this will really put him back on his feet depends on what the public does to help or hinder, on whether the community morally backs up the national program to put the disabled soldier beyond the need of charity.

In the past, the attitude of the public has been a greater handicap to the cripple than his physical disability. People have assumed him to be helpless, and have, only too often, persuaded him to become so.

For the disabled soldier there has been "hero-worship": for the civilian cripple there has been a futile kind of sympathy. Both do a man more harm than good.

All the cripple needs is the kind of job he is fitted for, and training in preparation for it. There are hundreds of seriously crippled men now holding down jobs of importance. Other cripples can do likewise, if given the chance.

In the light of results already attained abroad in the training of disabled soldiers, the complete elimination of the dependent cripple has become a constructive and inspiring possibility.

Idleness is the great calamity. Your service to the crippled man, therefore, is to find for him a good busy job, and encourage him to tackle it.

Demand of the cripple that he get back in the work of the world, and you will find him only too ready to do so.

For the cripple who is occupied is, in truth, no longer handicapped.

Can the crippled soldier—or the industrial cripple as well—count on you as a true and sensible friend?

The assistance of chambers of commerce and manufacturers' associations was enlisted to secure transmittal to their members, with a special note of indorsement by the organization, of a circular calling to the attention of employers their responsibility to the disabled soldier. Over two hundred thousand employers were reached direct in this manner and the statement was reprinted in scores of trade journals.

A speakers' bureau was organized, a film and picture service instituted, and the daily press and magazines supplied with informative articles on the work being accomplished abroad in the reconstruction of crippled men. One of the most interesting features of the work was the preparation for individual trade journals of articles on re-education in the particular trade covered by each journal or on employment opportunities for the disabled in that trade. This material proved of very direct interest to both editors and readers of the journals.

Another feature of the campaign was the issue of a booklet in ten foreign languages: Yiddish, Italian, French, German, Hungarian, Polish, Greek, Spanish, Danish, and Swedish. These were distributed to pastors of foreign-speaking congregations and to physicians and social workers in the foreign communities. The text of the booklets was also reprinted by almost every foreign language newspaper in the country.

The work of public education in the interest of the cripple has just begun. It must be continued until the "man in the street" is thoroughly familiar with his responsibilities to the disabled—until the community is converted from its present attitude.

311 Fourth Avenue.

BLINDED SOLDIERS AS MASSEURS IN HOSPITALS AND SANATORIA FOR RECONSTRUCTION AND REHABILITATION OF DISABLED SOLDIERS.*

By S. ADOLPHUS KNOPF, M.D. (New York and Paris),

NEW YORK.

PROFESSOR OF PHTHISIOTHERAPY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

From the addresses on the reconstruction and rehabilitation of disabled soldiers which were delivered at the annual session of the American Medical Association in Chicago† and from Lieut.-Col. E. H. Bruns' article on the tuberculous soldier (Journal A. M. A., August 3, 1918, p. 373), one may obtain a good insight into the work which Surgeon General Gorgas, his staff, and the Division on Reconstruction and Rehabilitation are contemplating. In his address on "Reeducation of the War Blinded" Lieut.-Col. Bordley says: "After the blind will have received a practical training they will get training in professional work, the trades, or agriculture," but I do not know whether he had in mind also the training of some of the blinded soldiers in massage. As no mention on this subject was made, I may be permitted to call attention to the fact that many a blinded soldier might, with relatively little training, become a skilled professional masseur.

Brigadier General Alfred E. Bradley, Medical Corps, U. S. Army, who recently returned from the front and with whom I communicated concerning the idea of employing blinded soldiers in this way, wrote me as follows: "In regard to the employment of the blind as masseurs, I think suitable men will find this occupation a very agreeable and remunerative one. Our people in America, however, do not utilize massage as freely, nor to such an extent, as we see it employed abroad. While in London I was very much interested to watch the work of the blinded men taking a course in massage instruction at St. Dunstan's. The superintendent informed me that they had no trouble at all in placing all the men in lucrative positions, who qualified in the course as it was given there.

"The experience of the French and English has been that for about every 1,000 men wounded there will be three men blinded; this, fortunately, is a rather small percentage and of this number prob-

†*Journal of the Amer. Med. Assn.*, June 22 and 29, 1918. All these addresses have now appeared in pamphlet form and can be obtained from the office of the Association.

ably only a small portion would be suitable as masseurs; I should think, therefore, that it would be necessary not to depend entirely upon the blinded soldiers as a source of supply for massage pupils and operators."

Dr. John A. Wyeth, president of the New York Polyclinic, suggested to me that, in a class of instruction in massage for blinded soldiers, there might well be included a number of soldiers who had received some injury to the lower extremities and other types might be found if the need for the work increased. It is particularly the blind that I wish to consider here, however, as there are so few occupations open to them. It is well known also that a blinded person develops a more delicate sense of touch than is usually possessed by the seeing, and this would certainly be an advantage in the work.

I have been informed by friends who have traveled extensively in Japan that there massage is exclusively a profession of the blind and that they develop a marvelous dexterity in manipulating muscles and joints for the cure or alleviation of many diseases.

As to the value of massage in certain nervous afflictions, in orthopedic and some surgical affections, I need not say anything. The utility of massotherapy in all these branches of medicine and surgery is well known, but not so much so in tuberculosis. I have, however, found it to be of invaluable help at that period in the life of the tuberculous invalid when his disease has been arrested, but when, owing to the prolonged rest-cure, his muscles have become flabby and his respiratory system indolent. Unfortunately, the expense of giving massage treatment in large hospitals for consumptives is prohibitive, but I have often used it with most satisfactory results in private practice after the return of the patient from the sanatorium as an arrested case. I have found massage to be of inestimable benefit at such times and excellent preparation for active physical exercise and work.

In fact, I go so far as to say that massage combined with carefully graded respiratory exercises and judicious hydrotherapy, skillfully and persistently applied for a period of from four to six weeks, is the best and perhaps the only means to guard the tuberculous invalid against the relapse. In so many cases, because of economic necessity, the arrested case resumes his former occupation before his muscular, respiratory, and cutaneous systems have regained sufficient strength to resist the deleterious influences of over-fatigue, atmospheric changes, the invasion of the pneumococcus, and minor respiratory infections to which the well man is immune. The policy of the surgeon general not to discharge the tuberculous soldier when the disease is merely arrested, but to retain him until his physical vigor is restored, is a guarantee that we will not have nearly as many relapses in military as in civil tuberculosis practice.

To return for a moment to General Bradley's statement that the physicians in this country do not use massage as freely nor to such an extent as we see it employed abroad, I must say that this observation is absolutely correct and is applicable to all branches of medicine, including tuberculosis.

During my recent visit to the Adirondacks I discussed the subject of massage with Dr. Edward R. Baldwin, the Dean of the Trudeau School, and Dr. Lawrason Brown, the well-known specialist and authority on tuberculosis. Both gentlemen were emphatic in their statements that massage is an important adjuvant in modern phthisiotherapy but one much neglected in this country. Dr. Brown stated as his opinion that we do not use massage frequently enough in tuberculosis—first, because we are strangely indifferent, and secondly, because it is too expensive. He also believes that it would offer a good means of livelihood to a certain number of blinded soldiers.

I submitted the draft of this manuscript to a number of other distinguished physicians, Prof. Hermann M. Biggs, State Commissioner of Health of New York, Dr. Thomas McCrae, Professor of Medicine of Jefferson Medical College of Philadelphia; Dr. Edward O. Otis, Professor of Tuberculous Diseases of Tufts Medical College of Boston, and Dr. David R. Lyman of the Gaylord Farm Sanatorium, Wallingford, Conn., until recently associate director of the Rockefeller Tuberculosis Commission in France, and the newly elected president of the American National Tuberculosis Association. Dr. Biggs writes: "I have read your article outlining a plan for the training of blinded soldiers as masseurs. It appeals to me strongly and I can see no reason why it should not be put into effect. I believe that massage is work which these men would be well qualified to take up." Dr. McCrae expresses himself similarly by saying that the suggestion of employing the war-blinded soldiers in that way was an excellent one and hoped that the Surgeon General's Department would take it up. As to the value of massage in tuberculosis, he regretted to say that he had not had opportunity to find out its effect on that class of patients, but that it would seem to him altogether likely to be very useful.

Dr. Otis wrote me as follows: "I have read the paper with great interest and approval. That the blind will and do make skillful masseurs I am sure for I have seen it. We have employed at the Boston Dispensary for some years a blind masseuse with great satisfaction as an example. Massage, I believe, is a valuable means in the post-sanatorium rehabilitation of the arrested tuberculous patient, and indeed, before that period in certain cases. I therefore heartily approve your plan of utilizing blinded soldiers. I believe massage could and ought to be employed in the treatment of tuberculosis much oftener than it is, but the reasons given in your paper are undoubtedly the causes why it is not. . . . I believe your paper is excellent in its suggestions as to the employment of blind soldiers and very timely when the rehabilitation and reconstruction of maimed soldiers is now under consideration and it has my hearty approval. The teaching of massage to blinded soldiers accomplishes two things —it helps the crippled soldier and renders possible the application of massage to the tuberculous more extensively than heretofore has been possible."

Dr. Lyman expresses himself as follows: "I

think your suggestion as to the training of blinded soldiers as professional masseurs an excellent one. Beside the wide field open to them in general medicine there would be the splendid opportunity in our new government sanatoria to give them special training in the application of massage to properly selected cases of tuberculosis. There is no question but that we have neglected this important branch of therapy in our work in America."

To the opinion of these eminent physicians let me now add that of Major Fred H. Albee, Professor of Orthopedic Surgery at the New York Post-Graduate Medical School and Surgeon-in-Chief of U. S. General Hospital No. 3 for Reconstruction, Colonia, N. J. He writes: "The training of our returning blinded soldiers in massage is most important work in the rehabilitation of the wounded soldier. I know of no task so valuable for the delicate touch of the blinded man and especially since individuals skilled in this work are so scarce and so many are needed as the rehabilitation of our disabled soldiers goes on."

My late friend, Dr. Herbert M. King, the regretted physician in chief of the Loomis Sanatorium, to whom I suggested the use of massage in his institution, gave it a thorough trial and assured me later on that I had been right in the belief that it would prove a most excellent means to overcome the tendency of muscular flabbiness and degeneration. Yet he had to discontinue it. At times he had nearly 200 patients and massage could be given to only a few and jealousy and discontent among those who did not get it forced him to abandon it altogether. It was not always easy to get expert masseurs who were willing to go to a sanatorium. Phthisiophobia had doubtlessly something to do with it.

If for the reason just given massotherapy cannot be carried out in an institution for the well-to-do, it is, of course, even more difficult to have it in hospitals or in sanatoria for the consumptive poor. Now, none of the difficulties raised by Dr. Brown's statement and those encountered in the experience of Dr. King concerning the application of massage to the tuberculous civilian, rich or poor, hold good when we are dealing with the soldier whose tuberculous lesion has been arrested or is quiescent so that massage will be truly helpful in preparing him for active exercise and work.

There will probably be a sufficient number of blinded or otherwise invalided soldiers who can take up massage as a profession. Phthisiophobia will not enter into consideration as a hindrance, for the soldier masseur will be instructed that no danger can come to him when dealing with the carefully trained invalid. The matter of expense to the Government when there is a question of rehabilitating the tuberculous soldier and making him a breadwinner again and a useful citizen is of course something which can be considered only as distinctly advantageous in the end.

Having had the opportunity to study massage and the Swedish movement cure in this country and abroad, I have taught these valuable therapeutic adjuvants to many of my pupils and nurses, and in cases where, for financial reasons, a professional masseur could not be employed, I have often succeeded in teaching a well member of the family how to apply the treatment to the tuberculous invalid. It was surprising to me to see how many men and women there are with a natural aptitude for this work. In some instances they developed into experts so that I could employ them advantageously in other families.

It is this experience which convinces me that many a blinded soldier might be advantageously taught the art of massage, not only as a way of earning his livelihood but also because he could do valuable work in our military hospitals for reconstruction and rehabilitation. Many masseurs will be needed in these hospitals and owing to the cessation of immigration from Scandinavian countries, there is already a dearth of expert masseurs. Later on, if there should be more masseurs than needed for military work, I am convinced that any well-to-do invalid in need of massage treatment will rather employ one of our blinded soldier heroes than an imported masseur.

Do I need to say that we physicians or surgeons, whether in military or civil practice, who have occasion to prescribe massage, would consider it a patriotic duty to help the blind soldier masseur to make an honest living by his newly acquired profession? He has given so much in comparison to the little we can give him in return.

On the evening of the day on which I was privileged to present this paper to the Academy, Lieut.-Col. James Bordley delivered a most inspiring address on the work which is being done under his direction in the U. S. Base Hospital No. 7, at Roland Park, Baltimore, Md. From the pictures shown by the Colonel, the institution seems to be exceptionally well placed and has already twenty inmates (sailors and soldiers) and the Colonel assured us that the morale of all the men is excellent, being doubtlessly greatly heightened by the generous provision of the government to have one relative of each patient live for some time on the hospital grounds to help and be present during the period of educational training. While all these blinded heroes regret that they had to leave the field of action "over there," they hope to be still of war service by aiding in the manufacture of ammunition. The plan in the hospital is to teach them to make small armatures, spark plugs, and so forth, and to train them in other trades and professions in which the loss of eyesight is not a hindrance to the attainment of the greatest efficiency. To my great satisfaction massage has been included among the professions to be taught to our blinded war heroes. This is but another evidence of the farsightedness of the Surgeon General and his staff and the thoroughness with which all work is done in that department.

16 West Ninety-fifth Street.

Legitimate and Illegitimate Children in Prussia.—In 1914 the number of legitimate births in Prussia was 1,067,408; of illegitimate births, 99,172. The death rate among the former was 2.85 and among the latter 4.47. The causes of death were congenital debility 35 per cent., diseases of the digestive tract 44 per cent, and the rest scattering.—*Nederlandsch Tijdschrift voor Geneeskunde.*

SOME OF OUR MEDICAL EXPLORERS AND ADVENTURERS.

By WILLIAM BROWNING, Ph.B., M.D.,

BROOKLYN, NEW YORK.

THE naturalist, the explorer, the adventurer, the pioneer, the missionary, the traveler, and the sporting man have something in common or make psychologically a continuous series. If we add medical training all along the line, then it can certainly be said that they represent a closely connected class. In other words, the grouping is an entirely natural and proper one, though it bring together apparently divergent characters.

The outside lines in which physicians attain eminence have an interest for us from many points of view—curiosity, history, information, the value and tendency of our training, etc.

Of these various activities in which medical men engage, in which their profession is a useful asset, and which at the same time have general interest, that of exploration, travel, and adventure has proved attractive in all modern countries. The physician is in fact specially qualified for this work—to guard himself and his fellows against disease and exposure, to take on executive duties, and to act as a valuable aid in ethnologic and other scientific observations, a multiple capacity. Seldom has any considerable expedition of this kind started without a selected medical man in the party, and not rarely he plays an important part.

Attention has been called to English physicians who have thus won distinction (editorial on "The Medical Explorer," *Lancet*, 1906, I, 106), notably such men as Mungo Park (1771-1805), James Stewart, James O. McWilliam, and David Livingstone. And that record might now be extended.

We also have those who have figured with éclat, though possibly our men have not always had as fine publicity agents. And as these phases of medical life are in part changing and unlikely to recur, a review may be the more timely. Especially at this period when so many are called to a new field there is added interest and incentive in the consideration of past exploits. It is easily possible to make a very creditable showing.

The word "some" introduces the title for a double reason. The list may well be incomplete. And then it is a question how far to go in framing up such a category. Many others have been explorers in casual and minor ways, besides those who have neither left traceable records nor found a friendly chronicler. And the use of the term explorer to designate all kinds of investigators is confusing; nor is the word "geographic" much more specific.

Even in pre-colonial exploration of America we find names of medical Europeans, as—Dr. Chanca, who accompanied Columbus on his second voyage, and whose letters give details and corroboration (v. Irving's "Life of Columbus"), and Thomas Dover, M.B. (1660-1742?), the rescuer of Alexander Selkirk, and cruiser along the western American coasts (v. sketch in Osler's "Alabama Student").

From early colonial times with us physicians have often been active in prospecting, pioneering, and the development of new settlements. This at times has included useful exploration, though usually of a local kind.

An early instance occurred within a year of the first settlement at Jamestown. In the summer of 1608 Capt. John Smith led two explorations up the Chesapeake and allied waters. In the first one, June 2 to July 21, was "Walter Russell, *Doctor of Physicke*," who headed a detail party, did the honors in a case of minor injury, and had his name applied to "Russell's Isles", though it does not appear on recent charts. The second, July 24 to Sept. 7, was accompanied by "Anthony Bagnall, *Chir*," who experienced the only near-accident, "shot in his hat by an arrow." Each medical man signed the report of his trip in Smith's "General Historie of Virginia, etc." (Vol. I, "The Third Book," chapter V, Richmond, 1819).

In further illustration it may be noted that many of the first or early governors of our States, provinces, and territories (at least fifteen) have been physicians, most of them with frontier work to their credit.

Naturalists and other scientific explorers comprise a further group. The earlier and systematic botanists especially did much distant prospecting, and were largely recruited from medical ranks. But among zoologists, even archeologists, anthropologists, orientalists, we find the names of men who have done work of an exploratory character. These pursue their activities along more or less traveled lines, with little detours into the unknown. Several of those in the subjoined list were primarily scientific explorers, and others so in part.

Customary accounts of some of these make little mention of their medical trainings (as Carver, Webber, Walker). The more reason for giving them our recognition as confrères.

It is often heroic work indeed that these men have engaged in. Some have perished at their labors—William Walker, Whitman, Webber, Houghton, Ambler. Others have suffered seriously in health or estate. Kane, who died in Cuba, may have thought to make up by tropic heat for sufferings from arctic cold! More, however, have lived to enjoy the records of their achievements, and some to a ripe old age,—Thomas Walker 79, Eights 86, Coates 84, Ruschenberger 88, Wisliscenus 79, Woodhouse 83, Henshall to 80 plus, and David Walker 79, besides some still active.

Hence eight of known age have lived to their eightieth year or beyond. Barring accident, it appears after all to be a long-lived cult. And it might well be expected that such a life would contribute to longevity.

Most of the members of this coterie have been likewise or subsequently prominent in civil or political affairs. Nor is this to be wondered at, if we recall the effect of travel and motation on intellectual development.

The modern extension of scientific training and the endowment of our museums have permitted these institutions of late years to dispatch collecting scientists on innumerable trips to every corner of the earth; with these the medical side is less in evidence. But we might here very well include those other explorers who, especially of recent times, have investigated diseases in their native habitats, so to speak. Of these we have such conspicuous examples as Ricketts (who sacrificed his life in Mexico), Walter Reed and his party in Cuba,

Ashford (of Porto Rico uncinariasis fame), Strong, and others.

Medical missionaries (as Whitman, White, Grenfell, *v. infra*) have also practically aided in work of this kind. In fact, missionaries and explorers are sometimes bracketed together. They, however, constitute so large and special a class that justice cannot be done them here.

Several of these men began as naval or army surgeons, and were billeted to do duty on expeditions. Some of them then became themselves trained leaders. This doubtless in part accounts for the considerable number of medical explorers. We know, however, that doctors take fondly to the wilderness, more so, perhaps, than most classes in the community.

Travelers range from the proverbial globe trotter to those who bring us useful studies of the remote and little known (peoples, places, things), and thus are sometimes in the explorer class. Our estimate must also depend somewhat on time and place; the man *e.g.* who in the early days penetrated a hundred or two miles beyond the frontier was far more notable than one who now journeys in comfort to Alaska.

Then there is the army of hunters, sportsmen, health seekers, and wanderlustige who are out for the zest of the thing. Naturally their contributions are not often of a character to place them in rank. It is pretty well understood that in this country our explorers soon had the benefit of accounts by trappers, missionaries, wild wanderers, and especially the Indians, where better guides were lacking. While such knowledge became more or less common property, it was so tinged with vagary and rumor as to have no authoritative value. It is only possible to recognize those as explorers who leave some tangible record.

It is somewhat a matter of individual view who shall be considered adventurers; that element may have been present to a degree in the case of many. The love of adventure is strong in all youth,—and some never grow old! And, if the adventurer ends with a record of great service to humanity, any uncertain aspects of his career are glossed over and he even becomes a hero of renown.

An allied instance is that of Benjamin Thompson, Count Rumford, who had advanced so far in a medical career as to be about entering practice when he forsook country and calling for political reasons. In the end he left a record of magnificent accomplishments, with scant blemish beyond lack of patriotism. By some he is reckoned an adventurer, and it requires no strain to approve his credentials for that grade. It is at least certain that his medical education furnished the basis for his later scientific and sociologic successes.

The more daring as well as the less successful specimens of the genus adventurer naturally cover up their trail, and in many cases we are left in doubt. There was James Wilkenson, an M.D. and beginning practitioner; then general in the Revolution; mixed up in cabals and uncertain episodes, including the adventures of Aaron Burr; yet who finally became Governor of Louisiana and general-in-chief of our army. Despite doubts and a trial or two it does not appear to have ever been settled how far he was "particeps," if at all, though medical psychology tells us he was at least "tarred" and close to the adventurer class, to put it euphoniously.

It is a bit remarkable that seven, and possibly more, were the sons of men who had also enjoyed a medical training (Eights, Webber, Suckley, Henshall, Ambler, Vincent, Cook), suggesting that, besides the above named factors, there is something special in medical life and heredity that gives an incentive in this direction.

It is further interesting to note that three of them very suitably bore the name of Walker! And that six were born in Pennsylvania, seven in New York, four in Massachusetts, two each in Connecticut and Virginia, three in Maryland, the others scattering, including four in England and three in Germany, *i.e.* distributed among the older States in fair proportion.

A considerable list of names can be gathered of those who in positive though unequal degree appear entitled to special recognition under our caption. The available memoirs of part of these are more brief than complete. An identifying outline follows, with sufficient excerpts of data to show warrant for their inclusion.

1. John Brickell, M.D., practitioner, explorer, naturalist, b. Ireland, settled for a time at Edenton, N. C., the then capital of the Colony. As head of a mission to the Cherokees in 1730 he took opportunity to explore western Carolina and "far into what is now Tennessee."

The Doctor returned to Ireland and published, "The Natural History of North Carolina, with an Account of the Trade, Manners and Customs of the Christian and Indian Inhabitants, Strange Beasts, Birds, Fishes, Snakes, Insects, Trees and Plants, etc." (Dublin, 1737): also, "Catalogue of American Trees and Plants Which Will Bear the Climate of England" (1739): various editions of each.

The first-named and principal work is now classed amongst rare and valued Americana. A copy of the first (1737) issue is in the collection of Dr. William C. Braislin of Brooklyn, and one of the 1743 issue is in the library of the American Museum of Natural History; the two copies are apparently identical except the date.

After an extensive account of flora and fauna (incl. pictures of many wild animals, small simple cuts as in a child's book, and yet perfectly recognizable and doubtless admirable for their time), Brickell gives, pp. 387-393, a most readable description of his expedition, beginning, "The latter end of February, Anno Dom. 1730, we set out on our intended journey, being in Number Ten *White Men*, and Two *Indians*, who served for our Huntsmen and Interpreters." "Our *Indians* seldom returned [from a hunt] without more that a sufficient quantity of *Venison*, *Wild Turkeys* and other Game for the support of all our Company." The trip lasted 32 days.

Martin's History of North Carolina, II, 4-9 (New Orleans, 1829) reproduces Brickell's description of his expedition, and says, "With a view to secure the friendship of the Indians, who were immediately on the western frontier of his government, he (Gov. Burrington) sent John Brickell, a physician, to meet them."

B. L. Robinson, of the Gray Herbarium, in "The

Doctors John Brickell" (*Rhodora*, 1916, Nov.) gives good reasons for concluding there were two of that name. The second John Brickell, M.D., was also born in Ireland, and prominent in like sciences, but lived a little later (1749-1809), and practised at Savannah, Ga.

The lapse of time, a quibble as to the spelling of his name, the few available copies of his work, the criticism (since refuted) that it contained little new, and the doubling of names have combined to obscure Brickell's status.

2. Dr. and Gen. Thomas Walker, A.B., 1715-94, born and lived in Virginia. He is the first recognized explorer of Kentucky (1750), preceding Daniel Boone by 19 years. He began as a physician, and (from his attendance on Jefferson's father) is presumed to have kept it up somewhat. He however also became a surveyor, married a rich widow in 1741, came into control of the fine property known as Castle Hill, and settled down to the life of an active Virginia gentleman.

In 1748 he "made an expedition through southwestern Virginia" and into East Tennessee. Then, as representative and surveyor of the Loyal Land Co. (whose agent he continued to be up to the Revolution), he started in March, 1750 on his famous trip lasting four months. The notes of this were published in full in 1898 by the Filson* Club of Louisville, under the title, "First Exploration of Kentucky.—Doctor Thomas Walker's Journal of an Exploration of Kentuckey in 1750." He entered by the Cumberland Gap, and traversed the "eastern part of what is now Kentucky." "Walker named the principal features of the country."

He was on other trips, commissions to the Indians, etc.; commissary general under Washington at Braddock's defeat in 1755; head of a commission that in 1779 ran the boundary line between Virginia and North Carolina 500 miles further west, "known as Walker's Line"; member of the House of Burgesses; guardian of Thomas Jefferson, patron of Joseph Martin who in 1769 started a settlement near Cumberland Gap; and is thought to have deeply influenced both Jefferson and Clark (the latter of the Lewis and Clark expedition). Walker was one of three who in 1778 gave the 120 acres for establishing the town of Abingdon, Va.

Besides other distinguished descendants, one son, Col. John Walker, for a brief period in 1790, was United States Senator from Virginia, and his 11th child, Hon. Francis Walker, was a Virginia Member of Congress (1793-95).

3. Jonathan Carver, 1732-80, born Connecticut. "Studied medicine."† Was captain in five campaigns of the French and Indian War (1757-63). Then "he undertook to explore the vast territory claimed by Great Britain in North America," and to find, as he says, "a North-West Passage, or a communication betwen Hudson's Bay and the Pacific Ocean."

He left Boston in 1766, reached Mackinaw, the remotest English post, and went on beyond the Mississippi. In 1767 he explored the north shores of Lake Superior. He visited twelve Indian tribes, lived as a native, and learned their language. He returned to Boston in 1768, having spent two years and five months, and traveled 7000 miles. Failing in Boston to secure a publisher, he went to England in 1769, and finally died destitute in London. He had arranged for a later expedition, but was estopped by the Revolution.

Carver had in no ordinary degree the personal equipment of an explorer. But promised supplies failed him, the country was poor and in political unrest, and possibly as the son of a British official he was pro-English. His dream of thus reaching the Pacific had to wait until the Lewis and Clark expedition of 1804-06.

He published two works, "Travels Through the Interior Parts of North America in the Years 1766, 1767, and 1768" (London, 1778), and "Treatise on the Culture of the Tobacco Plant" (1779). His "Travels" went through various editions in England and America, and was translated into French and German. "Carver's volume is still one of the most popular books of early western travel." Dr. Lettsom wrote his life in the 1784 issue, and aided his English wife and two children (he also had a wife and five children in America). Carver town and county and a cave and river in Minnesota are named for him. Carver Centenary in 1867 was celebrated by the Minnesota Historical Society. The query has been raised if, as the "good brother Jonathan" in an Indian treaty of 1767, he was not the original of our national sobriquet. His "description of the funeral of a 'brave' suggested Schiller's song, 'Nadowessische* Todtenklage" (1797-98). He proposed a system of internal waterways much as later realized.

Carver is our one early authority on Minnesota and the sources and upper basin of the Mississippi River. Much of this regoin was not traversed again by an explorer until Long's second trip in 1823.†

See "A Biography of Carver's Travels," by John T. Lee. *Procd. State Historical Society of Wisconsin*, 1909 (1910); also 1913.

4. Seth Reed, typical pioneer, born Rhode Island in 1744. First practised at Uxbridge, Mass. Was a colonel in the Revolution. In 1790 he went "to Ontario County, New York, where he acquired from the Indians a very valuable tract of land 18 miles in extent, known as the Reed & Ryckman location." In 1795 he disposed of that holding, went further west, and was the first white settler in Erie, Pa., where he ran a hostelry for newcomers, and died in 1797. v. Notice in Sanford's "History of Erie Co." 1862.

5. Dr. John McLoughlin, 1784-1857, born Canada. Was with the North-West Fur Co. as postsurgeon, and subsequently Governor of the Territory. Later he went across to the Pacific, and founded Ft. Vancouver and Oregon City, and is called the "Father of Oregon."

6. Dr. James Eights, 1796-1882, naturalist to the U. S. "Exploring Expedition of 1830;" artist, geol-

*Named for John Filson (1747-88), "the first medical man whose name is associated with the early history of Cincinnati," an explorer and medical student who was lost as his party began the settlement of that town.

†That Carver kept up his medical affiliations is indicated by his relation to Dr. Lettsom.

*Naudowesies (variously spelled), a name used at that time for certain Indians near the Mississippi. Schiller's title can best be rendered, "Nadowessian lament for the dead."

†Keating's "Narrative of an Expedition . . . in 1823," Philadelphia, 1824, I, 270 et seq.

ogist, also Indian explorer, but never in active practice. Born Albany N. Y., son of Jonathan Eights, M. D. See "The Reincarnation of James Eights, Antarctic Explorer," by Dr. John M. Clarke, in *Scientific Monthly*, 1816, Feb.

7. Edwin James, A. B., M. D., 1797-1862, born Vermont. "The earliest botanical explorer of the Rocky Mountains." Scientist of Long's first Expedition, and wrote the report, "An account of an Expedition from Pittsberg to the Rocky Mts., performed in the years 1819, 1820," under U. S. War Dept. (3 vols., Phila., 1823). He was the first to ascend Pike's Peak (to which Long gave James' name); surgeon U. S. A.; U. S. Indian agent; named the Ozark Mountains; translated the New Testament into Chippewa; prepared "Chippewa first lessons in spelling" (Boston, 1832); and wrote "Narrative of the Captivity and Adventures of John Turner," a U. S. interpreter stolen by the Indians (N. Y., 1830). "Compiled first list of Vermont plants." Obit. in *Annals Albany Co. M. S.*, 1864, I, 345-8.

8. Reynell Coates, M. D., 1802-86, b. Philadelphia, ship surgeon, scientific explorer, author, physiologist, medical cyclopedist, politician. Went to India and the Island of Mauritius, spending 5 months at Calcutta. Appointed scientist to a South Sea expedition that did not materialize. Professor of natural science at Alleghany College. Edited Godman's "Rambles of a Naturalist"; wrote "Reminiscences of a Voyage to India," and a once well-known poem, "The Gambler's Wife." He drafted the address of the Native American party in 1844, and in 1852 he was the nominee of the National American Party for Vice President of the United States.

9. Marcus Whitman, M. D., 1802-47, b. Yates Co., N. Y., practitioner, pioneer, missionary sent out by the American Board, "commissioned to explore Oregon"; self and wife massacred by the Indians. He early (1836) lead a party overland to the Pacific, and "opened the first wagon trail across the continent." By making in 1842-43 a forced ride across the country to Washington he was credited with saving Oregon to us,—though that conclusion is denied by some who term it the Whitman myth. Whitman's figure acquired such proportions and glamour as to be worthy of attack by the historioclasts. To the ordinary judgment, however, the evidence appears good, not only that he played a leading part in that matter of great importance to us as a nation, but that he was practically a martyr to the cause. Whitman College at Walla Walla was founded 1866 in his memory. His statue unveiled on a building at Philadelphia in 1897.

10. Dr. Elijah White,* first practised in N. Y. State, then a Presbyterian medical missionary to Oregon, and United States Indian agent west of the Rockies. He sailed from Boston in 1836; and went overland in 1842. "The first independent emigrating party of men, women and children—120—to that country was led over in 1842 by Elijah White, Indian agent for the government in the northwest. This was the company that informed Dr. Whitman of the negotiations for the Ashburton Treaty, and hastened him on his ride" (v. *Oregon*, by Barrows in "Am. Commonwealths," 1892.)

*This may be the first notice of Dr. White ever published. The Presbyterian Board in New York can "find nothing whatever concerning Dr. Elijah White."

He is best known from the following accounts: (*a*) "A Concise view of Oregon Territory, its Colonial and Indian Relations, compiled from official letters and reports, together with the Organic Laws of the Colony. By Elijah White, late Sub-Indian Agent of Oregon." Washington. T. Barnard, Printer, 1846, pp. 72. (*b*). "Ten Years in Oregon. Travels & Adventures of Dr. E. White & Lady West of the Rocky Mts.; with Incidents of two sea voyages via Sandwich Islands around Cape Horn." By Miss A. J. Allen, 1848, Ithaca, N. Y., pp. 399. (*c*). "Thrilling Adventures, Travels and Explorations of Doctor Elijah White, among the Rocky Mts. and in the Far West. Containing, also, a brief History of the Missions and Settlement of the Country—Origin of the Provisional Government of the Western Territories, Number & Customs of the Indians—Incidents Witnessed While Traversing and Residing in the Territories—Description of the Soil, Production and Climate." Compiled by Miss A. J. Allen. N. Y., 1859, pp. 430.

"Dr. White . . . developed a remarkable aptitude for organization of border communities into regular civic bodies." His early and later home was in Tompkins Co., N. Y., chiefly at Lansingville, alliteratively known in his younger years as Teeter Town.

11. Charles Pickering, M. D., 1805-78, b. Pennsylvania. "Principal zoologist" of the Wilkes' U. S. Exploring Expedition of 1838, and wrote a report. Later a well-known anthropologist and botanist; travelled in Africa and Asia; wrote on the distribution of man, animals and plants. Obituary by Ruschenberger, Proceedings, Phila. Acad. Nat. Sci., 1878.

12. Wm. S. W. Ruschenberger, M. D., 1807-95, b. New Jersey. As a surgeon U. S. N. he cruised extensively, in one trip sailing over 50,000 miles. Wrote "Three Years in the Pacific" (Phila. 1834), "A Voyage Around the World, incl. an Embassy to Muscat & Siam, in 1835, 1836 & 1837" (Phila. 1838, republished in England), "Notes & Commentaries during Voyages to Brazil & China, 1848" (1854), besides many scientific articles. Med. Dir. & Commodore U. S. N. Picture in Kelly's "Am. Med. Biogr." 1912.

13. Douglas Houghton, M. D., 1809-45, b. Troy, N. Y. Botanist and physician to Schoolcraft's U. S. expedition to the headwaters of the Miss. in 1831-32, and made a report; practised at Detroit (1832-37); projected the geological survey of Mich. and was state geologist (1837-?); prof. P. Mich. (1839-?), declining its presidency; explored south shore of Lake Superior; mayor of Detroit (1842-43); lost his life by drowning on a government survey. A town, a county and a lake in North Mich. and a school in Detroit are named for him.

14. Dr. John K. Townsend, 1809-51, b. Philadelphia. Wrote, "Journey Across the Rocky Mts. to the Columbia River" in 1832 (1839). Later to Sandwich Isl. and So. Am. Also ornithologist to Smithsonian Instn.

15. (Frederick) Adolphus Wislizenus, M. D., 1810-89, b. Germany. Political refugee to U. S. in 1835. Stopped in New York City, 1835-37, as "physician, political pamphleteer and poet." Then to Illinois, and by 1840 settled in St. Louis. The record of his expeditions is as follows: "A journey

to the Rocky Mts. in the year 1839. . . . Translated from the German, with a sketch of the author's life, by Fredk. A. Wislizenus, Esq., St. Louis, Missouri Histcl. Society, 1912." "Memoir of a Tour to Northern Mexico," Washington, 1848. At the instance of Senator Benton of Mo. the U. S. printed 5000 copies.

He went to Turkey in 1850, and then to Panama. From 1852 he remained permanently at St. Louis. He was largely actuated by scientific interests. His graduation thesis was on the crania of epileptics. His meterological observations and his collections in botany and mineralogy were prized. With Engelman in 1837 he organized "perhaps the first scientific society west of the Alleghany Mts.," and in 1856 the "Western Acad. of Science" of which he was president in 1858 & 1859.

"Gedichte von A. Wislizenus. Seiner Freunden zum Andenken von seiner Familie." St. Louis, 1890. His obituary in the *Lancet*, 1889, Nov. 2, says: "The 'Romance of Medicine' might well claim (him) as one of its heroes. . . . By all classes he was looked upon as an enthusiastic and large-minded reformer." Portrait and sketch in *Pop. Sci. Mo.*, 1898, vol. 52, 643.

16. James C. Palmer, A. B., M. D., 1811-83, b. Maryland. "In 1836 he sailed around the world." Was then surgeon of Wilkes' U. S. Exploring Expedition (1838-42). Wrote, "The Antarctic Mariner's Song." Surg. Gen. U. S. N.

17. Geo. L. Ditson, M.D., 1812-!, b. Massachusetts. Travelled in Europe, Asia and Africa (crossing the Caucasus Mts.), and wrote extensively thereon, later U. S. consul in Cuba; prof. of English at a college in Santo Domingo; never in active practice.

18. Charles W(ilkins) Webber, 1819-56, b. South Kentucky, son of Dr. Augustus Webber, studied medicine, then theology; and became a typical rover; author, Texas ranger, explorer, adventurer, journalist, editor of *Whig Review* in New York; killed in Walker's Nicaragua raid. Our S. W. was then new, and he used it for many frontier tales: "Historical & revolutionary incidents of the early settlers of the U. S., with biographical sketches of the lives of Allen, Boone, Kenton and other pioneer," pp. 416. "Old Hicks,the Guide; or Adventures in the Camanche Country in Search of a Gold Mine." 1848, pp. 356. "The Gold Mines of the Gila. A Sequel to Old Hicks, the Guide." 1849. "The Hunter-Naturalist. Romance of Sporting; or Wild Scenes and Wild Hunters." 1851, pp. 610. "Romance of Forest and Prairie Life, &c." pp. 228. "Tales of the Southern Border." 1853, pp. 400. "Wild Scenes and Song Birds." 1854, pp. 347. "'Sam;' or, the History of Mystery." 1855, pp. 550.

19. Elisha Kent Kane, M. D., 1820-57, b. Pennsylvania. Surgeon U. S. N., scientist, traveller, multimedallist; "surgeon to the first American embassy to China," explorer of the Philippines, "the first who descended the crater of Tael," traversed India, Egypt, West Africa, Mexico, etc. Senior surgeon of the first and leader of the second Grinnell Arctic expeditions. Wrote "The U. S. Grinnell Expedition." 1850-51 (1854), "Personal Narratives" (1852), and "The Second Grinnell Expetdition" 1853-55 (1856). Basin, Cape, Sea and Channel in the Arctic named for him.

Of all our past explorers, medical or other, Kane —though now dead over 60 years—still has a leading place in popular fancy He, in a way, appears to have been like Carver enmeshed in the joyism of our neo-psychologists. Biography by Dr. Wm. Elder, Philadelphia. 1858. Sketch and picture in Simpson's "Eminent Philadelphians," 1859.

20. Chas. C. Parry, A. B., M. D., 1823-90, b. England, educated here; botanist and explorer; made many trips discovering and collecting new plants in the Rockies and the whole far west. A peak in Colorado named for him. Sketch and portrait in Kelly's "Some American Medical Botanists." 1814.

21. William Walker, 1824-60, b. Nashville, s. of a Scotch banker; had a college course. First took up law. Next "studied medicine in Edinburgh, Paris and Heidelberg."* Became editor of the "San Francisco Herald." Then started on his career as the star ace of all our filibusters; appears to have been actuated in part by a desire to extend American influence; even winked at by our Government; though captured a couple of times by our officials, he was never really restrained.

In 1853 he fitted out a military colony for Lower California, nominally seized a region, and proclaimed himself its President. In 1855 he headed an expedition to Nicaragua, of which country he promptly became Secretary of War and Commander in Chief and had himself chosen President. In 1857 he was on another sortie there, and then in one to Honduras. In August, 1860, again to Honduras, captured, tried and shot.

He wrote, "The War in Nicaragua" (Mobile, 1860). His pictures make him resemble a modern professional man far more than an ideal buccaneer.

22. John L. LeConte, A.M., M.D., 1825-83, b. New York. Scientific explorer; trip as naturalist to Lake Superior and the upper Mississippi in 1844; to Rocky Mountains in 1845; explored Colorado River; collected fauna in Central America (twice), Africa, and Europe; Medical Inspector, U. S. A.; at one time our leading insectologist; president of A.A.A.S. and of Am. Entomological Soc. Bequeathed his entomological collections to Harvard. G. s. & g. g. s. of physicians.

23. Gustav Bruehl, M.D., 1826-1903, born in Germany, practised from 1848 at Cincinnati. "He spent many years in Central America, investigating the remnants of prehistoric races." Wrote "Die Kulturvoelker Altamerikas," "Zwischen Alaska & dem Feuerlande," and five books of poetry; also edited the "German Pioneer" (1869-71).

24. F. V. Hayden, M.D., LL.D., 1829-87, born in Massachusetts. Famous as the great developer of the U. S. Geologic & Geographic Survey of the Territories. Began in 1853 by exploring the "Bad Lands" of Dakotah, and again in 1854-56; geologist in 1859 to Warren's. Dakotah expedition and on a Yellowstone trip; surgeon in the Civil War, reaching the grade of physician-in-chief; professor University of Pennsylvania (1865-72); resumed Western work in 1865; from 1867 to '72 in survey of Ne-

*Although not noted in accessible sketches, it is evident that he was the William Walker of Tennessee, who in 1843 took his M.D. at the University of Pennsylvania. His graduating essay was on "The Iris," and, apparently a coincidence, he was later called "The gray-eyed man of destiny"!

braska, Dakotah, Wyoming, Montana and Colorado. From 1879 to 1886 "geologist in charge of the Montana division." Made many reports, including the first eight of the Survey. Also wrote "The Great West, Its Attractions and Resources," 1880; "North America," 1883. The Yellowstone as a national park is largely credited to him. He probably did more exploring, and was of more profit to our race, than any other one in this list, unless Dr. Robert Bell. I have been told that he was more of a politician than even scientist; at any rate, his wonderful success depended much on his ability to secure necessary Congressional appropriations. For sketch of his work, see *Sci. American*, 1888, Jan. 7.

25. George Suckley, M.D., 1830-69, born in New York City. Colonel and medical director, U. S. A., surgeon and naturalist of General Stevens' expedition to the Pacific (1853-4); wrote "Natural History of Washington and Oregon"; learned Indian languages; returned by way of Asia and Europe; in 1859 went to Utah and Pacific. Published a work on the Salmonidae. Son of John Lang Suckley, A.B., M.D.

26. Isaac I. Hayes, M. D., 1832-81, born in Pennsylvania. Surgeon to Kane's 1853-55 arctic party; then head of the 1860-61 expedition; again to Greenland in the *Panther* in 1869; gold medallist of London and Paris societies; surgeon in the Civil War; legislator (N. Y.). Author: "The Open Polar Sea" (1867); "The Land of Desolation," "Cast Away in the Cold," and Observations of 1860-61 (Washington, 1867). Also wrote on food values at low temperatures (1859). Sound, peninsula and cape in the Arctic named for him. Obit. in *Phila. M. & S. Reporter*, 1881, XLV, 740.

27. James A. Henschall, M.D. (1836-,) born in Maryland, son of a physician. Sportsman, scientist, superintendent U. S. Fisheries station, president of science and sports societies, writer on fish, fishing, and pisciculture, "Camping and Cruising in Florida" (1884 and 1888). Sketch in "Who's Who in America."

28. Robert Bell, M.D., C.E., F.R.S., etc., (1841-,) born in Canada. Chief of the Canadian Geological Survey; professor of chemistry, Queens University (1863-67); scientist of the 1884 *Neptune*, and 1885 *Alert* expeditions to Hudson Bay, and 1897 *Diana* to Baffinland; made vast surveys in British America and wrote innumerable reports; Bell River (a branch of the Nottoway) named for him. President of International Congress of Americanists (1906); gold medallist.

Dr. Bell appears to have accomplished more traveling, surveying, and describing of the wild northern part of this continent than any other person of record. For comparison we involuntarily think back to the somewhat similarly incisive work done by Hayden for this country.

29. Dr. Emil Bessels, 1847-88, a familiar name at one time, born in Germany. "Studied medicine and natural history"; accompanied Petermann's 1869 Arctic trip; chief scientist to Hall's *Polaris* expedition of 1870-73, and edited its scientific report; also in Dorst's and in Weyprecht's parties; secretary at the Smithsonian. Obit. in *Lancet*, 1888, I, 804; also by Dall, Trs. Phil. Soc., Washington, 1892.

30. James M. M. Ambler, A.B., M.D., 1849-81, lost on the *Jeannette* expedition of 1879-81; thought to have been the last survivor of the party that died "of starvation." "In the history of Arctic research there has been only one ship that was free from scurvy, this was the *Jeannette*," said Commander Melville, in tribute to Ambler. He was born in Virginia, the son of Richard Cary Ambler, M.D. Memoir in *Md. M. J.*, 1882-83, IX, 495-97. Picture and genealogy in du Bellet's "Prominent Virginia Families," 1907, I, 134 et seq.

31. Theophilus M. Prudden, M.D., LL.D. (1849-), born in Connecticut. Professor pathology P. & S., ethnologic popularizer. His writings include: "A Summer Among Cliff Dwellings," "An Elder Brother of the Cliff Dwellers," and "Under the Spell of the Grand Cañon" (1896); "On the Great American Plateau" (N. Y., 1906); "The Circular Kivas of Small Ruins in the San Juan Watershed" (*Am. Anthropologist*, 1914). The objects collected he has donated to the American Museum of Natural History.

32. A. Donaldson Smith, A.B., M.D., 1864-, born in Philadelphia. African explorer (largely under English patronage); medallist; author of "Through Unknown African Countries."

33. Edward E. Vincent, M.D., (1865-,) born in Ohio, son of John H. Vincent, M.D. Surgeon general, Illinois; surgeon Peary Arctic party of 1893-95; lecturer on ethnography. See Stone's "Eminent American Physicians and Surgeons," 1898.

34. Frederick A. Cook, M.D. (1865-,) born in New York, son of Dr. T. A. Koch. Arctic, Antarctic and Alaskan explorer, medallist, writer, lecturer.

35. Wilfred T. Grenfell, M.D., LL.D. (1865-,), the Labrador medical missionary, born in England, but much affiliated with this country.

Of many other worthy if less spectacular names from "Who's Who in Wanderland," a few may be mentioned, such as Henry W. Baxley, M.D. (1803-76), who wrote "What I Saw on the West Coast of North and South America and on the Hawaiian Islands"; Chas. Robinson, M.D. (1818-94), born in Massachusetts, first Governor of Kansas, whose centenary has just been celebrated; Adolphus L. Heerman, M.D. (1818-65), ornithologist on Pacific Railroad surveys; James V. Blaney, M.D. (1820-74), who in 1846 organized a successful mineral exploration of the south shore of Lake Superior, later president of Rush Med. College; Chas. S. Bruckner, M.D., 1821-99, of Baltimore, who practised in Africa and later was in the first party to enter the Yosemite; Samuel S. Woodhouse, M.D. (1821-1904), on Creek, Zuni, and Panama expeditions; Wm. L. Howard, M.D. (1860-1918), Arctic surgeon, author and medallist; W. Hunter Workman, A.M., M.D. (1847-,), born in Massachusetts, explorer, especially of Asiatic mountains and glaciers; and David Walker, M.D. (1838-1917), "last surviving member of the McClintock expedition" of 1857, writer, lecturer, naturalist, and surgeon, U. S. A., born in Irleand, died in Oregon.

Recent men, especially those who have come up in the present century, as Dr. Goodsell, with Peary in 1908-09, and head of one of his parties; the surgeons of the Roosevelt and the Bingham-Peru outfits, and Dr. Harrison J. Hunt of the McMillin 1913-17 Arctic expedition, may merit more specific mention in any future account.

54 Lefferts Place.

IPECACUANHA AND EMETINE IN THERAPEUTICS.*

By E. W. KOCH, M.D.,

BUFFALO, N. Y.

THE term ipecacuanha is derived from the language of the South American Indians, and implies vomiting root. Originally it was applied to a number of emetic roots, and for many years the botanical source of the variety, used with so much success in dysentery, was in dispute. Though the description given by Piso and Marcgraaf to one of two plants, believed by them to possess such virtues, fits in a general way the plant now recognized, it was not until 1800 that the matter was definitely settled. In that year a Dr. Gomez of Portugal, returning from Brazil, brought the first authentic specimens to Lisbon, and to him is accorded the honor of being the first to accurately describe the genuine plant. At the present time, the United States Pharmacopœia recognizes the varieties *Cephaelis ipecacuanha*, native to Brazil, and *Cephaelis acuminta*, indigenous to Colombia. There is little or no difference in medicinal qualities between these two forms, both yielding, on an average, 2.17 per cent of total alkaloids.[1] No drug has had a more interesting past, and the recognition it has won in the present assures it a future full of the promise of establishing itself as one of our most important remedial agents. In view of these facts, the following remarks seem justified.

Ipecacuanha has been used in medicine since earliest times.[2] It was being used as an emetic and as a remedy for bowel affections by the Indians of Brazil when that country was first settled by the Portuguese in 1500. Piso and Marcgraaf learned of it in their scientific exploration, and the account of its uses, together with a description of two varieties of a plant which they believed to be its source, appearing in their Natural History of Brazil, published in Amsterdam in 1648, is probably the first direct reference to it in the literature. In spite of the attention called to its virtues by these men, the drug was little used by Europeans until many years later. Le Gras, returning from Brazil in 1672, took some of the drug to Paris, but his attempt to establish its usefulness failed too, the large doses recommended damaging rather than aiding its reputation. A third attempt to introduce it into European medicine was made in 1686, the venture succeeding, and the drug gaining a foothold in spite of much opposition. In this year, a druggist of Paris named Garnier received a shipment of one hundred and fifty pounds of the drug. Having learned of its usefulness in dysentery, he gave some to his physician, Afforty, who, however, paid no attention to the claims made for it by Garnier. Jean Helvetius, a pupil of Afforty, was then appealed to, and, heeding Garnier's wishes, prescribed the drug in some dysentery cases. Meeting with the utmost success, Helvetius became very enthusiastic over this find, and forthwith advertised his successful treatment of dysentery with the new drug, which he sold as a secret remedy. The cures effected by him attracted much attention, and Louis XIV, hearing of them, ordered tests to be made of the remedy to verify the great claims made for it. Happily, these proved successful, and the King rewarded Helvetius by granting him the sole right of vending the new remedy. Some time later several of the court, including the Dauphin, were stricken with dysentery, and naturally Helvetius was called to attend them. Fortune again smiled on him, for the disease responded to his treatment, and his distinguished patients were made well. Louis XIV, thereupon, gave Helvetius 1000 louis d'or and accorded him the highest public honors, on the sole condition the remedy be made known to the world. Its reputation thus becoming established, it was much used, and proved, according to the early writers, of great service in the armies and hospitals. It was used in the form of a decoction in one to two dram doses, or as a powder in amounts ranging from thirty to sixty grains. Besides its use in dysentery and other bowel affections, it was employed for its emetic action, and in smaller doses for its nauseating, diaphoretic and expectorant effects. Its remedial qualities were believed to be due to resins and gums. For more than one hundred years following its successful introduction by Helvetius, the enthusiasm manifested for it at first having waned, no further progress was made, and the state of the knowledge concerning the drug and the disease remained practically stationary.

In 1817, one hundred and thirty-one years after the drug's introduction into European medicine, Pierre Joseph Pelletier isolated a substance from ipecacuanha which he termed emetine, Magendie's tests on dogs and man having shown it to have emetic properties. This same year marks the isolation of morphine, quinine, strychnine, and veratrine, and the greater interest taken in these, doubtless explains why emetine failed to receive the recognition due it. It was not until 1829 that we hear of it again, the medical profession's attention then being called to its value in dystentery, chronic diarrhœa and chronic pulmonary catarrh by Dr. James Bardsley of Manchester. Following this introduction of its empirical use in dysentery, many years were to pass before emetine was to come into general use. While its virtues were lauded by some, its uselessness in dysentery was emphasized by others. As a result we find most workers, until comparatively few years ago, continuing to prefer the whole drug.

Because of its apparent value in dysentery, Paul and Cownley,[3] in 1893, set about to remove from the whole drug the principle emetine, which Magendie had shown to be an emetic, believing the ipecac sine emetine might prove more efficient because the necessary large doses could be given without the danger of inducing nausea and vomiting effects, which too often made the oral use of the drug impossible. Their work resulted in the discovery that the emetine of Pelletier, until then considered a distinct substance, was in reality a mixture of several alkaloids, the principal ones being cephaeline and emetine. In the meantime, progress was also being made concerning the etiology of dysentery, for in the early nineties a dysentery of amœbic origin came to be considered a distinct disease.[4]

The years subsequent to the days of Helvetius have seen the ipecac treatment pass through periods during which it was alternately lauded as a specific

*Read before the University of Buffalo Alumni Association, June 5, 1918.

and condemned as useless in dysentery. Men of recognized standing favored, while men of equal rank opposed its use. Such was the state of affairs in 1910, when Vedder[5] undertook to determine the reason for this divergence of opinion. Testing several preparations of ipecac on various bacteria and on non-pathogenic amœbæ, pathogenic amœbæ not being cultivable as yet, he demonstrated, for the first time, by laboratory experiments, their inhibiting influence on the growth of the bacteria and their destructive action on the amœbæ. A de-emetized preparation of ipecac was found to be inactive, while emetine proved to be more powerful as an amœbicide than any of the preparations of the whole drug. His findings indicate the inconsistencies of the past to be due, in part at least, to the use of drugs variable in strength and their employment in all forms of dysentery regardless of the cause.

The introduction of the drug into the body, up to this time, was possible only through its oral or rectal administration. In spite of all measures tried to overcome them, the irritating effects too often made its use by these methods impossible. On this account, after extending Vedder's observations by proving the amœbicidal effects of emetine on the *Endamœba histolytica*, isolated from dysenteric stools, Leonard Rogers,[6] in 1912, decided to try giving the hydrochloride of emetine hypodermically, believing, if this method proved practicable, the greatest drawback to the use of the drug would be overcome. His tests proved in a striking way the possibility, and to him belongs the credit of successfully introducing the hypodermatic use of the soluble salt of emetine into medicine. He also proved it could be given intravenously and gave one grain of the salt without any bad results. The dangers of this method have, of course, kept it from coming into general use, but the observation is interesting from the standpoint of what it teaches regarding the drug's toxicity. In passing, it might be well to note, in 1913, Walker and Sellard's success in experimentally producing endamœbic dysentery in man, and thus conclusively establishing the pathogenicity of the endamœba histolytica.

The year 1914 proved another eventful one in the history of ipecac and its alkaloids. Barrett and Smith[8], having found endamœbæ constantly present in the pus pockets of a series of pyorrhea alveolaris cases, and believing them of etiological importance, introduced the local use of emetine hydrochloride for its amœbicidal effects, and while it was impossible for them to prove the pathogenicity of the endamœba absolutely according to the rules of Koch, they believed in this indirect way to have secured positive evidence for their contention. Some months later Bass and Johns[9] confirmed the original findings, and also believing in the pathogenicity of the endamœba, used emetine hydrochloride hypodermically with the greatest of success. They also tried giving a new preparation of ipecac (alcresta ipecac) by mouth, and the results obtained testify to the efficiency of this method. When it is remembered that up to this time it was practically impossible to give ipecac by mouth without inducing nausea and vomiting, the value and possibilities of this new method become apparent. Bass and Johns in their enthusiasm considered the *Endamœba buccalis* the sole exciting cause, while Barrett and Smith, more conservative in their views, recognized spirochetal and bacterial pyorrheas, besides the endamebic type. Other workers,[10] however, held opposite views, believing the endamœba not only harmless, but even of benefit to the host. The attention of dental and medical workers everywhere came to be focused on the subject, and the literature for months contained many comments, some favorable and others critical of the findings and conclusions of the original workers. As yet the problem has not been definitely settled. That ipecac and emetine have been of undoubted value in the treatment of many cases of pyorrhea alveolaris cannot be denied, while their failure to be of help in other cases must be admitted. Those favoring the ipecac treatment do not claim it alone will cure the disease, but consider it a valuable adjunct to the local dental instrumentation the two together constituting a rational treatment in the light of our present knowledge. Those opposing it point to the failures as positive proof that an amœbicide is contraindicated in all cases, ignoring or denying the many authentic cases of success reported. These apparent inconsistencies will, no doubt, in time be explained, and the usefulness of ipecac and its alkaloids definitely established.

The status of ipecac therapy has changed very little during the last two years. We find, therefore, the rational employment of ipecac and emetine continues to be almost entirely for the amœbicidal effect, though each also enjoys a deserved reputation as an expectorant. The beneficial effects reported following this treatment in non-amœbic conditions remain inexplicable, but suggest a possible broader scope of usefulness than the drug enjoys at this time. Our knowledge concerning its pharmacology has, however, been advanced, and though it is far from complete, it has not only given us a better understanding of the proper use of the drug, but has also suggested a new theory regarding its mode of action in the body.

Ipecac owes its activity to three alkaloids which in the inverse order of their importance are psychotrine, cephaeline, and emetine. All produce pharmacological effects that are similar in kind but different in degree. Psychotrine is present in traces only, and though it has a very low toxicity, its relatively poor amebicidal property renders it unimportant from a therapeutic standpoint. Emetine is present in the largest amount, and by virtue of its lower toxicity and greater amebicidal powers is preferred to cephaeline. Following its extensive employment in endamebic infections in recent times, there have appebared, especially during the last two years, quite a few reports[11] regarding its great toxicity. A consideration of the toxic action of the drug is therefore desirable.

The value of any effective drug is first of all determined by the difference between the dose necessary to produce the desired action and the toxic dose. Clinical trials have shown that the hypodermic use of one-half to one grain of emetine hydrochloride daily, for at most from six to about ten days, suffices to destroy all active endamœbas in most cases. In this dosage, unless the patient is unusually susceptible, the drug gives rise to untoward effects. A single course of treatment of longer duration is entirely uncalled for and should not be undertaken.

The minimal lethal dose of emetine for man is not definitely known, no authentic case of fatal poisoning from a single dose having been recorded. A few fatalities as a result of the continued use of the drug have, however, occurred. Dr. A. L. Walter[1] basing his figures on one such report and animal experiments, estimates the probable single lethal dose for a man of seventy kilograms to be not less than 10.8 grains, while Dalimier[12] concludes from animal experiments that the toxic dose for a man of 54.5+ kilograms is about 27 grains, whether it be given in a short period or during several weeks. Compared with the fatal quantity of some of the other commonly used active alkaloids, the toxic dose of emetine is surely a very large one. While large doses are rarely used, and probably never indicated, it is interesting to know Allan's[13] patient, aside from becoming nauseated and vomiting once, suffered no other ill effects from a single injection of 4 grains of emetine hydrochloride.

In animals, the too long-continued use of small doses of emetine hydrochloride produce effects which suggest a cumulative action.[1] In man the prolonged use of therapeutic doses of the drug produces a like action, and constitutes the real source of danger in its employment. Many clinical reports indicate, however, that this action is of such a nature as to permit of complete recovery if the danger signals—beginning depression, intensified diarrhea, neuritis, etc.—be heeded and the use of the drug discontinued. For instance, among the cases reported by Murphy and Johnson,[14] is one who received twenty-two grains in as many days. Toxic symptoms were manifested but complete recovery followed the discontinuance of the treatment. And Lyons[15] tells of a physician who took twenty-one and one-third grains in sixteen days. General muscular weakness and pains in the legs developed, but these effects were gradually recovered from, when the use of the drug was stopped.

The many thousands of cases in which emetine has been used without ill effects, and the comparatively few fatalities that have been recorded, prove the drug not to be so dangerously toxic as some would have us believe. The difference between the usually recommended dose of one-half to one grain of emetine hydrochloride daily for six or eight days, and the toxic dose, which is probably not less than one grain a day for about twenty-two days, assures a margin of safety permitting the use of the drug, as recommended, in average beings, without any great risk.

One other development must be mentioned. Until quite recently it was generally believed ipecac and emetine produced their good effects in endamebic infections by a direct action on the endamœbæ. Dale and Dobell,[16] however, in a recent report, bring forward evidence which seems to disprove such a theory, and leads them to suggest "the therapeutic efficacy of emetine is a result of its action upon the host rather than upon the parasite." These findings, while probably undermining the theory of the drug's mode of action suggested by Vedder's original work, do not, in the least, detract from the value of the manifestations of the action of the drug, established by the success attending its empirical use in former years, and its rational employment in more recent times.

Remarks.—Ipecac and emetine are efficient drugs and their employment is rational in all endamebic infections.

Emetine, when used as recommended, appears to be as safe as any other effective and potent drug.

AN EFFECTIVE TREATMENT OF LOBAR AND BRONCHIAL PNEUMONIA, ALSO OF INFLUENZA AND ITS COMPLICATING PNEUMONIAS.

By W. B. HOLDEN, M.D.,
NEW YORK.

It is not the purpose of this article to discuss in detail the causes, symptoms, and complications of the various types of pneumonia. It is conceded, however, that the disease is of bacterial origin, in most cases the generally accepted organism causing the disease being the *Diplococcus pneumoniæ*, of which four types, called respectively I, II, III, and IV, are recognized. They are not infrequently associated with other microorganisms, especially streptococci, staphylococci, the bacteria of influenza, and sometimes the bacillus of Friedlander. The gravity of the cases depends upon which one of the above pneumonic types is present, and whether or not it is associated with one of the latter groups. Friedlander's bacillus occurs in about 5 to 10 per cent. of the cases, and almost exclusively in late

adult life; seldom in children. It is very fatal, and the bacillus can be found in the blood in the early stages of the disease. Its demonstration is important as regards prognosis. No type of pneumococcic serum would have any specific influence on this bacillus. At present we will deal only with the two forms of pneumonia, lobar and bronchial, including also those cases complicated by the presence of streptococci, staphylococci, and the influenza bacillus. In bronchopneumonia we have an associated streptococcus infection with which to deal.

Complications other than those resulting from direct infection from the disease should be treated according to recognized methods. Where the pneumonia is the direct cause of the complications, the treatment to be suggested will generally be sufficient. Empyema and meningitis can frequently be treated by aspiration and lumbar puncture respectively and the direct application of the colloid as described below.

In reference to symptoms and diagnosis, it is presumed that the diagnosis of pneumonia, with or without complications, has been made, therefore the symptoms and differential diagnosis will not be considered in this article.

Several methods of treatment are in vogue, the older consisting chiefly of symptomatic treatment, viz., Heart stimulants, general hygiene, dietetics, hydrotherapy, etc. Some of the older methods are still considered useful and applicable. The selection of such means as are necessary to combat special symptoms can be left entirely to the discretion of the physician. Specific treatment, so called, requires more consideration.

At the present time, the generally accepted procedures of specific treatment are along the lines of vaccines (autogenous and stock), pneumococcic serum of the older types, and the newer serums developed along lines dependent on the differentiation of the four bacterial types of pneumococci. Types I and II, where differentiation of the types is possible, and the appropriate serum is obtainable, are reasonably responsive to serum treatment. Serums for types III and IV are recognized as having little or no value. Of the other forms of so-called specific treatment one or two deserve special mention.

The synthetic product, ethylyhdrocuprein, or optochin, is accredited with having specific bactericidal action on the diplococcus of pneumonia; it is open to the objection of sometimes producing toxic effects, though some very favorable reports regarding its value have been made.

The use of the salts of quinine, applied according to the method of Solomon Solis-Cohen, is credited with some desirable results. The use of camphor in oil injections in large doses, according to the Seibert method, is also reported to have given good results.

The pneumococcic vaccines (autogenous or stock), although credited with specific effects, have seemed, in my experience, to be too slow in their action.

The plan of treatment that I would suggest in these cases has, in my own experience, been productive of nearly 100 per cent. cures. I have found it applicable to the usual types of pneumonia, lobar and bronchial, also the type of pneumonia complicating influenza. In streptococcic infection, which is frequently associated with the so-called septic varieties, in which extreme prostration, high temperature, rapid pulse and respiration, delirium, stupor or coma, are present, is almost equally effective. I refer to the metallic colloidal solutions alone, or combined with bacterial derivatives. The use of metallic colloids alone in pneumonia and other infectious diseases is not new. Etienne and others, as long ago as September, 1907 (*Revue Médicale de l'Est*), reported favorably on their action. The use of metallic colloids combined with bacterial derivatives is, I believe, original, and in many instances it seems to be a decided improvement.

A metallic colloid is an ultramicroscopic suspension of positively and negatively charged particles of metals in a state of constant motion (the so-called Brownian movement), and possessing the properties of natural body colloids, of which the blood serum is the most imporant.

In their physicochemical properties they resemble the natural colloids, viz., in their antitoxic and fermentative properties and their effect in producing leucocytosis and thus stimulating body resistance.

The properties of antitoxins, the function of agglutination and digestion, must be regarded as due to the action of colloids. As evidence of their applicability, I would refer to an article by Dr. J. W. Jobling and Dr. William Peterson, entitled "The Non-Specific Factors in the Treatment of Disease," published in the *Jour. Am. Med. Assn.*, June 3, 1916.

The subject of purely chemical substances of an inorganic or metallic nature, so transformed by chemical or electrical means as to resemble in their mode of action, lack of toxicity, and physicochemical properties, substances of a purely organic nature, and to have similar bactericidal, antitoxic, catalytic, and fermentative properties, is apparently not very well understood.

It seems probable that the action and beneficial effects observed from these substances, metallic colloids, and specific antitoxins and vaccines, are based on a similar mechanism in all cases. In view of these facts it would seem possible that the various agents act as stimulants of hematopoiesis, and, as a consequence, the organism is suddenly flooded with antibodies, thereby overcoming the infection.

If this is the mechanism, it is important to keep in mind that the stimulus itself is not a specific factor, but that the hematopoietic system has been attuned to respond to the non-specific stimulus with the production of specific substances.

"It seems probable that the fundamental change on which the majority of the above described biologic reactions are based is one of colloidal dispersion, in that the injections bring about a less dispersed state affecting not only the serum proteins but also the serum lipoids. Such an alternative is sufficient to account for the fluctuations in the ferment and antiferment balance, and in the coagulation mechanism, as well as in the opsonic and complement process of the serum; although it does not at present explain the increased antibody titer." (Jobling and Peterson, *loc. cit.*)

With this as a basis, we can understand that many and diverse substances of a non-specific char-

acter, viz., metallic colloids, might be capable of producing specific antibodus in pneumonia and influenza, and thus make a non-specific treatment capable of producing specific therapeutic results.

It has been my experience, extending over a period of several years, that colloidal silver alone, or colloidal gold combined with bacterial derivatives, is able to combat successfully the progress of pneumonia. The usual method is the intramuscular or the intravenous injection of colloidal silver at intervals of four to twenty-four hours, according to the amount of reaction, accompanied by the internal administration of adrenalin chloride in doses of five to ten minims at intervals of two to four hours, according to the necessities of the case. In cases where the symptoms are not relieved by the following method I have frequently obtained results by combining bacterial derivatives (Schafer) with two to four times the amount of colloidal gold used subcutaneously (not intravenously), and repeated at intervals of twenty-four hours. If used intravenously it must be preceded by a subcutaneous injection and the initial dose must not exceed 1/5 c.c. of the bacterial derivative and the colloid. The rest of the treatment consists of the usual hygienic and dietetic measures and of treating the complications as they arise, according to the indication present. Expectorants and heart stimulants are to be given, if found necessary. Essence of pepsin, combined with guaiacol and syrup of ammonium hypophosphite, seems to be of some benefit as expectorants and in diminishing the gastrointestinal disturbancess so frequently encountered.

Conclusions.—In view of the fact that pneumonia is the result of a pneumococcus or combined infection, and that differentiation not only of the various pneumococcic types but also of the associated organisms, is necessary, and that such differentiation is not always possible; and further, that the appropriate serum may not be obtainable after the differentiation is made, it would appear reasonable to make use of chemical substances, nonspecific in nature, which are capable of producing clinically specific results. The metallic colloids are some of several substances capable of producing this specific therapeutic reaction, and they possess the great advantage of being of themselves absolutely nontoxic. Furthermore, their use does not in any way interfere with subsequent specific serum treatment, and their application does not require previous differentiation of the organisms present.

If investigation of the character of the type of pneumococcus should indicate specific treatment, and the same should be employed as the metallic colloids would still be indicated as having a general appliability to other varieties of infection frequently associated with pneumonia, viz., streptococcic, staphylococcic, and influenzal. Therefore, they are at least deserving of trial while awaiting the determination of the type of pneumococcus and its associated infectious organisms, if any be present.

The fact that they are at the disposal of any practising physician, and do not require an elaborate technique for their administration or special after care of the patient, even though the treatment is not a strictly specific one, speaks strongly in favor of their employment.

The use of metallic colloids is not suggested as a substitute for Type I serum when differentiation is possible, but as a treatment having real value, as demonstrated by experience when specific treatment is not available or is inapplicable. It has the further advantage of producing an almost equal effect on other organisms occasionally present, viz., the influenza bacillus, streptococci, etc.

The frequent repetition of colloids adds much to their efficiency, and the use of water in large quantities proves a valuable addition in the treatment of the toxemia. An aid to the practicability of frequently repeated treatment is the use of water holding the metallic colloids in suspension, which may be taken in the absence of the physician.

A METHOD OF HEALTH CONSERVATION.

By GUSTAV F. BOEHME, JR., M.D.

PSYCHIATRIST, EDUCATIONAL CLINIC, COLLEGE OF THE CITY OF NEW YORK; NEUROLOGIST, WEST SIDE GERMAN DISPENSARY; ASSISTANT, NEW YORK NEUROLOGICAL INSTITUTE; FORMERLY MEDICAL EXAMINER, METROPOLITAN LIFE INSURANCE CO.; MEDICAL EXAMINER, AMERICAN TEMPERANCE LIFE INSURANCE CO.; POLICE SURGEON, CITY OF NEW YORK.

THE physical condition of the average young American has always been of interest to the educator and the public hygienist. The various boards of health have pointed with pride to their lowering death rates, especially if the figures in the infantile death rate column became less and less per thousand. All of this has, however, had to do chiefly with "mortality"; the question of "morbidity" is a somewhat different problem, and only careful school examinations have to some extent helped reduce conditions that mean ill health and lack of efficiency on the part of the growing up man or woman.

The recent draft examinations have shown, however, that all past methods of preventive medicine have not been as effectual as had been supposed, for the percentage of rejections and the number of men fitted only for limited military service was surprising. It would seem, therefore, that more careful methods of physical examinations, of recording data, and of repeated reexaminations of children and adolescents are called for. Already various means are being devised to prevent further physical "unfitness" on the part of the future American citizenry.

It is the purpose of this article to suggest one other method, one which the author has considered of tremendous importance for at least a period of three years before the entrance of the United States into the war, but which, there being apparently no necessity therefor, had repeatedly been rejected by those to whom his plan was suggested.

Some of the larger insurance companies in this country (to wit: the Metropolitan Life, the Prudential, and the Hancock companies) insure children from one year upward; they also insure for larger policies adolescents between eighteen and twenty-one years. Besides this they have a system of industrial insurance, a system by which individuals who are limited in means can insure for sums as low as five cents weekly. In this way they reach the poorest class of patients, those who, if ill, utilize our clinics and our hospitals to the maximum extent.

It is the office of the insurance examiner to ex-

amine apparently normal individuals, and decide not alone their state of health at the time of the examination but also their prospective likelihood of good health and life throughout the duration of the policy applied for. He decides these facts by careful observations and a knowledge of mortality statistics as related to each condition discovered. Of all phases of medicine his is unique in that he must primarily know what constitutes *good health*, and separate it from disease conditions (the primary problem of the practicing physician).

After he has completed his examination he forwards his report to the executive medical board of his company, and that, guided by definite actuarial tables, decides for or against the risk.

All this is done in secret, and the applicant rarely if ever knows why he has been rejected; in fact, frequently becomes incensed, believing himself to be in good health, against all forms of insurance. The examiner may find an inherent cardiac condition, a potential interstitial nephritis, even a tuberculosis. The applicant only knows "I was rejected."

The flaw in this scheme has seemed to the writer to be that here are potential invalids, so markedly so that the insurance company cannot take the risk of granting them insurance. They are given no guidance; no suggestion is made to them of how to regain health or to live so as to conserve their impaired constitutions.

Destructive criticism, however, is of little help. Constructive criticism may be valuable. The writer would suggest a scheme whereby the health of all would-be insurees could be conserved, and whereby, as insurancy begins at one year, a great deal may be done to prevent the lamentable showing in our first draft of physical unfitness. He would advocate:

1. That a central health conservation board, under the auspices of the State Board of Health or the State Superintendent of Insurance, be established.
2. That to this board every rejection on the part of insurance companies be reported, with a complete record of all the data.
3. That every rejected individual receive from this board a card giving him the reason for his rejection, with the advice that he consult his physician or the nearest hospital or clinic. To this card should be attached a second one for a reply from that physician or the hospital consulted, which it shall be statutory that that physician or institution return to the Health Conservation Board.
4. That a yearly follow-up card be mailed to each reject for a report of his status at this time.

As an experiment it might be interesting to go over the rejection lists of the large companies to discover how many cases of tuberculosis diagnosed by their medical examiners have been reported to the health boards. The secrecy of their system, to date, has kept them safe from observation, and yet the State Tuberculosis Report Law does not exempt them from this duty, for the law distinctly states "all cases of tuberculosis must be reported by the examining physician" (and he, in the insurance field, is acting only as an agent for his medical board). The author himself has in four years' examinations, disobeying the law of the insurance company, sent at least twenty-five tuberculous patients to clinics where they have been properly attended.

Pre-tabetic conditions, incipient nephritis, suspected tuberculosis, myocarditis, slight endocardial conditions are discovered in the adult—to be neglected unless these individuals are guided aright.

In children, the deformities of rickets, the signs of spasmophilia, the enlarged tuberculous glands, the oral defects are glossed over by a rejection. It should be the duty, the lawful duty, of the insurance organizations to guide these children. It is interesting, it is valuable, it is proper that books of child hygiene be distributed by them to the insuree; they are healthy at the time of the examination, and it is "good business" to protect these well members of the insurance family. Much greater is the call to help these poor, usually almost poverty-stricken, children whom the examiner has rejected to regain a sound body.

Medicolegal Notes.

Selling Morphine Without Prescription—Effect of Opium on Witness.—Appeal was made from a conviction of selling morphine without a physician's prescription. Evidence was admitted on the trial of various alleged illegal sales of morphine by the appellant to four persons other than the prosecuting witness. Offered evidence of a medical expert was refused, this evidence being offered to show the effect of morphine upon the mental condition of a person addicted to its use, as was the prosecuting witness at the time of her purchase of the drug from the appellant and her arrest. Instructions were refused which directed the jury to view with caution and suspicion the testimony of prostitutes and drug users. Error was predicated upon these matters.

The Washington Supreme Court, in reversing the judgment of conviction, said that there is no more insidious and dangerous testimony than that which attempts to convict a defendant by producing evidence of crimes other than the one for which he is on trial, and such testimony should only be admitted when clearly necessary to establish the essential elements of the charge which is being prosecuted. To establish guilty intent, unlawful motive, or criminal knowledge, it is permissible to show that the act charged against the defendant was one in a series of similar ones; but beyond this the state cannot go, and for the purpose of securing a conviction show the perpetration of other similar acts, even though committed in furtherance of a general scheme, where there is no proof required to establish intent, motive, or knowledge, other than proof of the act charged itself. In other words, where the act charged against the defendant itself characterizes the offense, the guilty intent is proven by proving the act. Here the proof of giving of dry morphine on a prescription calling for morphine in solution was proof of the intent, and nothing more was necessary to establish criminality.

The evidence of the state having shown that the prosecuting witness, a sporting woman, was under the influence of morphine at the time of the alleged sale to her by the appellant, and that she was arrested then by an officer to whom she related her story, the defense was entitled to prove, by expert testimony, the effect of the drug upon the mind and memory of its user.

While testimony is admissible to show the character of or effect of the use of drugs upon a witness as affecting his or her credibility, it is not proper for the court to violate the constitutional provision against commenting upon the evidence by instructing the jury that it should regard the testimony of any class of witnesses with caution or suspicion.—State v. Smith, Washington Supreme Court, 174 Pac. 9.

Military Medicine.

Early Stages of Trench Nephritis.—In the *Bulletin of the Canadian Army Medical Corps* for September, 1918, Major G. S. Strathy describes phases of the early stages of trench nephritis. It is pointed out that while microbic infection is almost certainly the cause of the disease, predisposing causes probably play an important part. The problem of the predisposing cause has given rise to many theories and suppositions. The epidemic is more prevalent on the Western European front than the other fronts and it is more common among the British than the French troops. McLeod and Amenille (*Lancet*, September 9, 1916) found that the percentage of men having albuminuria was higher among British than French troops. The urea excretion was also higher among the British.

Various theories were advanced to explain these facts. Exposure and fatigue due to army life were suggested as a cause of albuminuria. Chlorinated water and immature beer were said to damage the kidneys. However, Strathy found nothing to suggest that these were predisposing causes of epidemic nephritis. Several men were affected who were sleeping in warm, dry billets, and did not do any heavy manual labor. Possibly the high protein diet of the British soldier predisposes him to attack. Strathy's records do not show age as a predisposing factor. Very few men were attacked during their first three months in France. Several Australians developed their first symptoms while on board ship coming from Egypt. While there is probably some relationship between epidemic nephritis and the high percentage of albuminuria found in healthy troops both in France and England, it is almost certain that these cases of unexplained albuminuria are not mild cases of epidemic nephritis. It would seem likely that there is an extra strain thrown on the kidneys of the British soldiers which predisposes them to an attack by a microorganism which is prevalent in the army abroad.

The symptoms, according to Strathy, divide the diseases into three main clinical types: (1) Mild cases with albuminuria and few subjective symptoms; (2) hematuria cases with symptoms pointing to affection of the lower part of the urinary tract, and (3) nephritis cases with edema. It is often difficult to differentiate mild cases of epidemic nephritis from albuminuria due to other causes. The test on which most reliance is to be placed is blood pressure. Nearly all cases of mild nephritis, even without edema, have an increased blood pressure in the early stages. Few, if any, of the other albuminurias have increased blood pressure.

The second type, hematuria, comprises a smaller class and under the term hematuria Strathy includes only those cases in which hematuria is marked and there is no edema. Rise of blood pressure is not always present and is never marked.

The third clinical type, comprising those usually sent to the clearing station with a diagnosis of nephritis or bronchitis is the most important for it includes all the severe cases. This type resembles in most respects the acute nephritis of civil life, but shows important differences. Bronchitis, edema, hydrothorax, and ascites are more marked features than are toxic symptoms, such as headache, drowsiness, vomiting, and convulsions. The lack of symptoms due to cerebral poisoning by chemical products is an outstanding feature in over 90 per cent. of the cases. Suppression of urine is seldom marked. Rapid disappearance of acute symptoms is usual.

Nearly all the severe cases admitted to hospital were markedly dyspneic due to bronchitis and fluid in the pleural sacs. This marked tendency to affection of the lungs and pleurae and the unequal distribution of the edema in the body is, says Strathy, the most conspicuous feature of the disease in contrast to nephritis of civil life. So much indeed is this the case that it may be doubted if the disease should be classed as a nephritis, but should rather be described as a proliferative endarteritis of the smaller vessels affecting different organs with varying severity in different cases. Treatment advocated is as follows: Rest in bed and a simple diet of milk and milk puddings will effect rapid improvement in the large majority of cases. The symptoms calling for active treatment are cough, dyspnea, decrease of urine, headache, and convulsions. If a patient is markedly edematous or his blood pressure high a hot-air bath is indicated. The patient's bowels should be kept fairly free with Epsom salts, but purging should be avoided. If dyspnea do not subside after such treatment inhalations of oxygen almost invariably give considerable relief. Aspiration of the hydrothorax is indicated in some severe cases.

Strathy thinks that opium in any form for relief of cough is strongly contraindicated. Its administration appears to increase cyanosis. For convulsions spinal puncture and withdrawal of fluid was employed with good results, due in the belief of Strathy to the removal of poisons from the fluid. French observers have reported excess of urea in the spinal fluid and Strathy holds that spinal puncture should be done either when an attack of convulsions is threatened or as soon after the convulsion as possible. The mortality from the disease is everywhere reported as low.

Report on a Series of Gassed Cases.—Major S. G. Ross and Captain A. T. Henderson, C. A. M. C., publish a report on gassed cases in the Bulletin of the Canadian Army Medical Corps for July, 1918. As for the effects of gas on the gastro-intestinal system it is stated that vomiting was a fairly constant symptom, being present in 60 per cent. of cases; 10 per cent. had nausea without vomiting. Several complained of retching. Vomiting often was the first symptom, coming on as early as five minutes after gassing. In other cases it was not complained of until two days later. Certain men did not vomit until food was eaten. The stomach appeared to be irritable for some days after the men had been gassed. Abdominal pain was complained of by 19 per cent. It was nearly always referred to the epigastrium, and was stated to be of a steady, burning character. Only one man had crampy pains. Diarrhea occurred in 2 per cent. of the series. Twenty-four

per cent. showed definite skin lesions, and one-half of these had blistering. The remainder showed burns of the first degree only. Burns were noticed as soon as nine hours after gassing. The blistering was often extensive and severe. Seventy-eight per cent. of the cases complained of headache at one time or another. Headache was moderately severe. A few men suffered from dizziness. Three men gave a history of collapsing or fainting. A number of cases complained of weakness and pains in the muscles. One man only showed definite jaundice. Forty-three cases had a temperature of 99° or more on admission, and of these thirteen had a temperature of over 100°. Bronchitis was present in ten cases, and the fever of the remainder might be accounted for by laryngitis or burns. Eleven per cent. had a pulse of 90 or over. A few cases only showed increased respiratory rate.

Iodine in the Treatment of Gassing.—Bondreau, who is apparently a partisan of the use of iodine for a variety of affections, such as tuberculosis, many infections, enteritis, etc., believes that this remedy possesses remarkable powers in the treatment of gassed subjects. According to an abstract in the *Journal de médecine et de chirurgie pratiques* for August 10, the drug is especially adapted for the reconstitution of the damaged lung through its powers of promoting leucocytosis, its stimulation of glandular secretions, its antitoxic properties, and its power of stimulating the myocardium. It is also a remarkable general roborant and is a valuable synergist in systemic depression of strychnine, camphor, ether, etc. It must be given in very large dosage in fractional portions. The author prefers the tincture, which mixes readily with various liquids, as milk, tea, beer, etc., and may therefore be incorporated in all of the patient's daily fluids. In this way the patient may ingest 7 or 8 daily doses. One begins always with very small doses, as one drop; on the next day two drops, and on the third, three are given. The tolerance which develops enables a patient to take most formidable doses and in tuberculosis the author has pushed the daily dose to 300 drops and even to 500 and 800. The individual dose may be run up with impunity to 60 drops. In gassed subjects he has gone as high as 400 drops of the tincture daily. No clinical data are given in support of the author's claims.

Dry Pleurisy at the Front.—Lesage, in a recent Paris thesis reviewed in the *Journal de médecine et de chirurgie pratiques* for August 10, states that not infrequently men who are exposed to cold and damp at the front begin to complain of symptoms afterward found to be due to dry pleurisy. These men complain of their sides, shoulders, liver, kidneys, spleen, etc., and examination reveals the presence of a more or less abortive lesion of the pleura, the sole symptoms of which are pain and a friction sound. The question at once arises whether we are confronted in a given case with a tuberculous or a simple pleurisy from exposure. In the former the tendency is to involvement of the upper lobes, subfebrile temperature, tenacity of symptoms, slight and characteristic physical signs comprising subdulness on percussion and increased conduction of vibrations of the chest wall when speaking. The general condition is inferior. On the other hand, the subject with pleurisy from exposure is usually in a good physical condition, gives a history of exposure and of a cold, has chills and a true fever and complains of pain referred to any of the localities already referred to. The symptoms are soon over —for they last but three or four days as a rule. The pains are regional and the patient will often indicate with his finger the exact spot at which the friction sound will be heard. In tuberculous pleurisy this is apt to be otherwise, the sensations being more general and vague. The treatment consists of cups and quinine, perhaps with antipyrine. The author appears to believe that these cases are sterile in type and due purely to exposure, the left side being somewhat more often attacked because more frequently exposed.

Primary Interventions in War Surgery.—In an article in *Le Progrès Médical* for May 4, by Demmler, attention is first called to the remarkable study by Professor Delorme on secondary suture of nerves which shows the possibility of obtaining in a majority of cases an ultimate good functional result. So far so good but the question at once asserts itself, might not a primary intervention do away with the necessity for months of incapacity and trophic changes? What is true of nerves holds good equally for muscles, tendons, and bones.

Recently Sieur has made suggestions for improved transport of wounded to the rear, so that primary interventions are favored. In 1912 it was shown in Arthus' laboratory that immediate exact suture of a cut nerve should be followed by downward proliferation of the central end of the cylinder into the sheath of the degenerated portion. This confirmed the old teachings, which seem to have been set aside as a result of unfavorable experiences in the Russo-Japanese War. During the present conflict favorable results of primary suture have been reported—for example by Tavernier and by Tanton. The operation was performed as late as twenty-four hours after injury.

In immediate suture of bone the interest centers on the detached fragments of bone. It was once the teaching to remove all such and eventually surgeons went to the extreme of conservatism. A middle course seems best. Small, projecting spiculæ should be removed, and perhaps also those denuded of periosteum. Free fragments of any considerable dimensions must be saved, lest the loss of so much tissue result in a false joint. It is easy to disinfect these and this should always be the practice else the fragment may become a sequestrum. In some cases one may reconstruct a bone by suturing together so many free fragments that a veritable mosaic results. This course appears to be the one in actual use by a large number of surgeons. The reconstructive procedure is sometimes termed osteosynthesis. The use of circling bands is naturally indicated in these cases.

A similar practice is recommended for wounds of muscles and tendons, which could be termed patching up. It was recommended by Lejars in his work on surgical emergencies. It is after seeing the disastrous results of waiting that one is resolved to do something at once. Left to heal, the muscles shorten and become fused with other tissues. Nat-

urally cases for primary intervention have to be selected by first excluding wounds in which the tissues are hopelessly disorganized. The selection depends on the possibility of restoring continuity and securing attachments. In some cases tendons can be reunited by end to end suture while in others implantation can be effected. In the case of muscles it is often possible to secure enough tissue for primary suture.

Chronic Sinusitis in Soldiers.—In the *Archives Médicales Belges* for July, Sterckmans relates ten cases of sinus disease illustrated with photographs and radiograms, and concludes as follows: These affections are very common, and while it is usually easy to locate an acute sinus inflammation, the reverse is true if the disease is chronic. This difficulty is due largely to the fact that in chronic affections we are often dealing with a polysinusitis. Treatment of these cases must be active and energetic and we must not shrink from opening up these cavities whenever such a course is indicated and even when drainage seems to be absent. The diagnosis must be exact and we should use every diagnostic resource available. Thus the author makes a thorough use of radiography and with good results. The method is very commonly neglected, but he cannot understand why for he finds it quite indispensable, especially in ethmoid disease. He has utilized the expert services of a colleague instead of trying to do his own work. There is considerable objection on the part of the soldier for fear of a bad cosmetic result, and even members of this profession are not without apprehension of this sort. The latter is unfounded, for in the great majority of cases healing of the operation wound takes place by first intention.

New Hospitals in the Riviera.—The American Red Cross announces that 30,000 beds are ready for American wounded in a series of new hospitals established in southern France under the command of Major W. H. Browne of Detroit. Hospital units composed of American physicians and nurses are being sent to Nice and other cities along the Riviera.

Red Cross Work in Near East.—Another of the American Red Cross series of reports has just been issued showing how the society's war fund is being spent in Russia, Siberia, the Balkans, Syria, Armenia, and other sections of the Near East. In European Russia, to date, the American Red Cross has spent $2,807,919. More than one-half a million dollars was devoted to buying milk for the starving babies and children of Petrograd. The fund supplied 125 motor ambulances to Russian hospitals as well as large quantities of medical and surgical supplies. In recent months more than $120,000 has been spent in the relief of refugees in Switzerland and Siberia. In July, $1,511,233 was spent for several thousand tons of food, drugs, and soap among returning Russian prisoners. In Siberia $4,273,200 has been expended, the greater part being for clothing. A hospital of 250 beds for the accommodation of Czech wounded was equipped at a cost of $10,000. In Roumania in the six months between September, 1917, and March, 1918, $2,676,369 was expended; for work in Serbia $1,244,197 has been appropriated; for the relief of refugees in northern Greece $429,596 has been spent. For the maintenance of a hospital at Vodens $30,000 was appropriated and $48,598 was given for a dental contingent to serve the Serbian Army. Fifty thousand dollars was contributed to the Serbian Red Cross. For Greece $375,000 has been appropriated, and for Armenian and Syrian relief an aggregate of $3,000,000 was contributed.

Influenza in Army Camps.—According to reports from Washington, on October 18, the number of influenza cases was slightly on the increase, after having shown a decrease for several days. The total number of influenza cases reported from all camps up to the above date numbered 279,945, the pneumonia cases 42,675, and the deaths 13,681. It is the belief of army surgeons in charge of military camps, where every single case is known and kept under observation, that the death rate from influenza is 5 per cent., and it is believed that this proportion may be accepted as reasonably accurate in civil life.

Sinusoidal Current Banned from German Military Hospitals.—The *Wiener medizinische Wochenschrift* records that the Ministry of War, having learned that several deaths have followed the use of the sinusoidal current in the treatment of war neuroses, has forbidden its use in military hospitals. The faradic current alone may be employed. It seems that the fatalities were as sudden as chloroform fatalities, and that they occurred soon after the current was applied. Status lymphaticus is said to have been found at the autopsies in such cases.

Ohio to Care for State's Wounded.—Ohio soldiers from overseas are to be cared for while convalescing by the State of Ohio at the State School for the Deaf. Other hospitals for convalescents are to be established at Lima, Dayton and Cincinnati.

Municipal Civil Service Commission to Protect Red Cross Nurses.—An effort is being made to amend Section 22a, Chapter 211, of the Laws of New York, which provides that persons in the Federal, Military, Naval or Marine Service, whose names appear upon all eligible lists, shall be placed upon a separate eigible list for the same position for a period of one year from the date of their honorable discharge from such service, so that the same privilege may be extended to Red Cross nurses as are enjoyed by the armed forces of the United States.

Lieut. Leo J. Crum, M. C., U. S. Army, of Kalamazoo, Mich., has received the Distinguished Service Cross for extraordinary heroism in action near Clerges, France, on July 31 and August 1, 1918, "where by his untiring efforts under fire he saved the lives of many wounded and suffering men and was a source of inspiration to the entire command."

Deaths in the Service.—LIEUT. ROBERT HARRY SCOTT, M. C., U. S. A., of Brooklyn, N. Y., a graduate of the Long Island College Hospital, in 1910, died of pneumonia on October 15, aged 33 years. He was a surgeon in the United States Navy assigned to the Naval Rifle Range at Peekskill, N. Y.

LIEUT. COLEMAN SIMPSON SIFF, M. C., U. S. A., a recent graduate of the University and Bellevue Medical College, and an interne in Bellevue Hospital, died of pneumonia at his home in Bath Beach, L. I., on October 20.

THE MENINGITIDES AND ZONAS.

OF all the symptomatic zonas, that of tuberculosis at present appears to be the most individual of all. In chronic tuberculosis, spinal or pulmonary, one quite frequently encounters herpes zoster, and particularly a relapsing zona occurring in successive crops. The thoracic form predominates, although it may appear in other regions. The extrathoracic forms of zona are interesting because they indicate that this process is not an extension in the neighborhood of the tuberculous lesion, but a secondary involvment of the nervous system by the bacillemia. In this case the prognostic value of zona is considerable, but although it thus proves the diffusion of the bacillus and preceded serious meningeal localization of tuberculosis, it may very well be the first symptom of an unsuspected tuberculous process. In these circumstances it is the index of a mild meningitis which may be recovered from, although examination of the cerebrospinal fluid and general and nervous disturbances leave no doubt as to the true nature of the affection. In all such cases the ganglion and root are involved, but perhaps more often acted upon, in the mild cases, by the toxin than by the bacillus itself. The fact that tuberculosis may thus pass over the meninges and end in a local recovery is one of the most interesting which has been brought to light by the study of bacillary zona.

The mild involvements of the meninges are classic in syphilis and zona is frequently a symptomatic manifestation of the process; but one must not confuse symptomatic syphilitic zona with zoniform syphilides of the tertiary period which have nothing in common other than their localizations, the eruptive element being quite dissimilar and with a torpid evolution. Zona has also been met with in locomotor ataxia, a fact easily understood, given the essentially radicular nature of the affection. The meningitis of mumps is to-day well known and zona may accompany it. Certain affections are normally accompanied by an eruption of herpetic vesicles which is in itself an important diagnostic element. The most characteristic are those encountered in pneumonia and cerebrospinal meningitis.

Dermatologists have established an absolute difference in histological characters between zona and herpes zoster. Instead of a reticulated degeneration, as in herpes, zona offers a fibrinous degeneration accompanied by a process of ballooning degeneration. The vesicles are not trabeculated. From the pathogenic viewpoint it hardly appears doubtful that the nervous system is at the bottom of the trouble in both processes, but data are wanting to show beyond question that herpes results from a distinct lesion of the nervous system, while zona is the first dermatoneurosis in which the relation of the cutaneous lesion to the nervous lesion has been demonstrated. Nevertheless, more or less zosteriform herpetic eruptions may accompany pneumococcia and they are classic in cerebrospinal meningitis.

In the group of meningeal states recalling cerebrospinal meningitis, but differing from it bacteriologically, attention should be directed to the researches of Dopter, Simon, Achard, Lober, and others, who have attempted to isolate and grow cultures of the agent of essential zona. Their conclusions are that they were dealing with meningitides due either to a diplobacillus or to a strain of *Bacterium coli* producing symptomatic zonas. They also doubt the existence of an essential zona, because at the present time only the study of biological reactions is capable of demonstrating this entity. In all symptomatic zonas arising in meningeal states the commencement with the meningitis is proved by the time elapsing between the two processes, from two to five days' interval existing between the appearance of the zona and that of the meningitis.

It is only necessary to mention the causes of zona other than meningitis, because the symptoms of the various causal affections are always sufficiently evident and distinct so that an erroneous interpretation as to the pathogenic relationship cannot occur. Perhaps influenza, scarlet fever, measles, typhoid fever, rheumatism, intoxications, and neoplasms are not the etiological causes of zona, but merely adjuvant causes, preparing the soil for the invasion of true zona. In chronic affections, as for example neoplasms, the relapses may perhaps cause one to reject the latter hypothesis, but in the case of acute infections it seems logical to assume that only the discovery of the pathogenic agent of essential zona can solve the problem.

INTESTINAL OXALIC LITHIASIS.

THE pathological phenomena present in intestinal oxalic lithiasis are of divers sorts. If some, such as pain and vomiting, can possibly be explained by the mechanical and chemical action of the gravel on the intestinal mucosa and therefore are the consequences of simple lesions, there are others, such as vertigo, paleness, asthenia, etc., which

precede the paroxysm and represent the early manifestations of oxalemia before the organism has been able to localize the elimination, after having passed through a phase of tolerance and latent toxic accumulation. The violent pain of intestinal colic has been particularly noted because, given the large caliber of the intestine and the small size of the calculi or gravel, it is astonishing that accidents almost equal to those of intestinal occlusion should arise. Foutel attributes them to enterocolitis, founding his supposition on the presence of similar painful manifestations occurring in the latter affection, although gravel cannot be detected in the stools.

In conformity with his ideas on inflammatory lithiasis, Chevallier is of the opinion that this may be likened to those met with in pyelonephritis, latent in the first place but becoming painful as soon as a secondary calculus forms. Moreover, he believes that the painful irradiations along the transverse colon may be explained by stasis in the gut, while the stasis itself can be readily understood when the frequency of enteroptosis in mucomembranous enteritis is recalled.

But if this explanation is to be admitted for lithiasis due to lithogenous catarrh, it is not admissible in the case of oxalic lithiasis in which the accidents of enteritis are absent. Although admitting, perhaps, that both mechanical and chemical lesions may exist, Loeper believes that the pain is not entirely due to the elimination of the sand, but also to the congestion caused by the intensive secretion of the oxalates by the intestine. This accident may be compared to those encountered in gout and in point of fact the crystals of calcium oxalate form in the glandular culs-de-sac where their presence provokes real disorders, just as the precipitation of calcium oxalate *in situ* in the mucosa causes true miniature oxalic infarcts with their resulting hemorrhage, which consequently is not due to erosions only. It is for this reason that the pain always begins in the epigastrium and offers the characters and irradiations of solar plexus pain. A certain number of reflex symptoms may be explained by simple lesions of the intestinal mucosa, but the majority of the others are the direct consequence of the decalcification of the organism.

Many researches have shown the peculiar affinity of the oxalates for calcium and in point of fact during the evolution of oxalic intoxication the percentage of lime in the organic fluids is increased. Thus in one case Loeper and Béchamp found 0.095 gram calcium per liter of fresh blood, this being twice the normal percentage. Likewise, the amount of calcium eliminated in the urine and feces is increased. The experiments of Sarvonat and Rebattu have shown that during oxalic intoxication decalcification commences at first in the soft tissues, the calcium content of which becomes 0.10 instead of 0.17, and it is only later that the skeleton commences to lose its calcium salts; but if elimination continues, the line of the bones drops from 0.49 per 100 to 0.37. Decottignies has shown that by injecting animals with both oxalates and phosphoglycerate of calcium in sufficient quantity at the same time, the former become almost inoffensive. Likewise, by giving calcium chloride to animals the paralysis of their hind legs and oxalic cachexia are prevented after they have been poisoned by the oxalates.

This subtraction of calcium has as a consequence a certain number of disturbances which have been studied by Arthus, Gley, and other observers. Sometimes they are local disturbances, such as spasms of the colon, simple or painful, constipation and mucorrhea; at other times they are of a general nature, mostly neuromuscular. That oxalic acid has a particular affinity for muscular and nervous tissue is shown by the researches of Locke and Howell, who have demonstrated that a muscle placed in a 0.70 per cent. solution of sodium oxalate loses it motricity and regains it only after calcium sales have been added, and several writers have shown that brain matter fixes oxalic acid in almost the same way as it does the toxin of tetanus. It is most probable that the intimate mechanism of the action of oxalic acid can be explained by a more or less brutal decalcification of the viscera. This then explains the asthenia, cardiovascular disturbances, particularly the arterial hypotension, and the nervous phenomena. The profound denutrition produced by subtraction of lime also explains the loss of weight which is almost constant in these patients.

But if decalcification suffices to explain the nervous and muscular disturbances or even the cardiovascular disturbances it does not throw any light on the origin of the anemia and the leucocytosis. Therefore, for the time being, at least, a toxic element of some other nature must be admitted which is as yet insufficiently known.

HEADACHES OF NASAL AND MASTOID ORIGIN.

Some few years ago headaches were by some extremists attributed almost exclusively to eye strain, although the symptoms in perhaps the majority of cases did not warrant this diagnosis. Undoubtedly eye strain does play a conspicuous rôle in the causation of pain in the head and is, on the whole, probably the most frequent cause or contributory cause of this condition. But an undue amount of attention was paid to this theory and other agencies calculated to produce similar results were overlooked.

The need for a clear and correct causal diagnosis is obvious, and in order to obtain this a comprehensive knowledge of the very large number of causes which produce headache is necessary, else the practitioner is too apt with the view of relieving the acute symptoms to prescribe sedative drugs. As a rule, this kind of

medication, in the long run, does more harm than good. It causes relief from pain, but not a cure, and the sufferer learns to rely on drugs to his ultimate undoing. If the physician had diagnosed the origin of the pain he would have been able to attack it with every hope of bringing about a cure. It has been pointed out on many occasions recently that a frequent cause of headache is inflammation affecting one or more of the nasal or mastoid sinuses. Sluder lays stress on the fact that headaches and eye disorders of nasal origin are numerous.

William Ibbotson, writing in the *Practitioner* for September, 1918, discusses headaches of a sinus origin and describes the position and characters of headache due to disease in the various nasal or mastoid sinuses. For example, the position of a headache in acute ethmoidal sinus disease is (a) frontal, chiefly on the same side as the lesion, especially if the anterior set of ethmoidal cells are involved; (b) occipital, if the posterior set of ethmoidal cells are affected. Such headaches are dull, aching, often throbbing, and a feeling of heaviness over the bridge of the nose is more or less constant. In an acute maxillary sinusitis the headache is on the same side as the lesion and pain is referred to the incisor, canine, and premolar teeth, to the lower eyelid, the side of the nose, and the cheeks and upper lip. The pain is throbbing in character over the site of the inflammation and is acutely neuralgic following the course of the superior maxillary nerve after it has entered the inferior orbital fissure.

The Significance of Marbled Nails.

There are numerous minor diagnostic symptoms and signs which the observant physician notes, and which sometimes greatly aid him in arriving at a correct diagnosis or prognosis. In fact, the ability to observe such symptoms and signs, to tabulate them, and to apply to each its value as a means of coming to a conclusion is in great measure what differentiates the skillful from the ordinary physician. It is certain that effective treatment cannot be given unless the diagnosis is correct, and it is only by acute and comprehending observation of various minor points that the physician is able to say with any degree of certainty what the originating cause of the malady is and to attack it at its root. In the *Medical Press* of August 7, 1918, Dr. R. Sabouraud of Paris discusses the prognostic symptomatic significance of "marbled nails." Marbled nails—that is, finger nails with one or more small white patches—are nails on which there are multiple transverse white patriæ, and according to Sabouraud are of definite diagnostic and prognostic significance. In men, marbled nails are less frequently met with than in women, but on the other hand they are more characteristic. They are usually associated with the pretuberculous period, with neurasthenia, and with chronic alopecia. Sabouraud has met with it in its maximum degree in the subjects of exophthalmic goiter, accompanied by alopecia, in whom it seemed to follow the oscillations of Graves' disease, and ran its course alongside the latter, so to speak, hand in hand. It is, he says, a bad symptom, though it is not a grave symptom, because we see persons who present it for years and years without any notable depreciation of health. It is, however, a symptom which is never met with in the really healthy subject. It is accompanied by a lowered blood pressure and other symptoms of physical and mental depression. It is never an accidental product, and its presence corresponds to a tangible departure from perfect health, or, at any rate, it only occurs in subjects who sooner or later are likely to develop something—exactly what, it is not in our power to state for the time being. In short, the existence of marbled nails is a danger signal, not only demonstrating in the apparently healthy a latent weakness or susceptibility to disease, but also in conditions of poor health an augury that serious results may ensue. The presence of marbled nails, therefore, should serve to put physicians on their guard.

Food Stringency and Its Consequences in Germany.

Extracts from the German lay periodicals concerning the food situation are published from time to time in *La Presse Médicale*. In the September 9 issue it is stated that dog thefts are common, the animals being used for food—not so much a necessity as a luxury, by reason of the scarcity and high price of fresh meat. Dressed dogs bring fabulous prices in the market as a substitute for game, which is no longer seen on sale. Naturally the production of sausages constantly increases and offers opportunities for using everything edible as well as much which is doubtless unfit for food. Milk is frozen into large blocks and handled like ice to facilitate transportation. The largest weigh 60 pounds. This milk ice can be kept sweet for several weeks. The crop of pulses and fruits has suffered from the drought and from caterpillars. Edible fungi are to be salvaged under government supervision. Much of the sugar crop has to go for alcohol. Sodium benzoate tablets are sold in the market for housewives' canning purposes. To conserve potatoes alcohol is made from shavings, etc., which are transformed first to glucose by means of sulphuric acid. On the fighting front seeds, draught animals, and farming machinery are requisitioned from the conquered Belgian and French farmers. The cereals in these zones go to the German civilians with a portion of the potatoes. The forage, straw, beets, etc., go to the German army. In this way at least 100,000 transport wagons are released for war purposes. The salvage of dried leaves has become an industry of much importance. They are milled and mixed with molasses as a succedaneum for oats for domestic animals. Recently there has been a plague of abortion in cows and it is attributable to a germ against which a serum is used. Rabies in dogs is prevalent and suspected animals are at once killed—even stray dogs are supposed to be destroyed at sight. At last accounts there were 20,000 cases of cholera in Petrograd, so that the German troops have been vaccinated against it. Infant mortality is up and has been brought

in direct causal relationship with the house fly, against the eggs and larvæ of which a campaign has been conducted.

Biopsy in Cancer.

It is somewhat instructive to observe with how great unanimity authorities on cancer agree as to the harmfulness of biopsy. Though advocated as a means of diagnosis by the late Commissioner of Health of New York City, the danger of following such advice has been emphasized by surgeons throughout the country. Lieut.-Commander Jerome M. Lynch, writing on cancer of the rectum in the *International Journal of Surgery* for September, 1918, states that he is unalterably opposed to biopsy, as it tends to disseminate the growth and serves no useful purpose, in that the liability to err is just as great as it would be with one unfamiliar with the characteristics of the growth. It is also known from experience that even the rough handling of a tumor is very often sufficient to disseminate the cells, and so much more certainly is the cutting into it harmful. The teaching that biopsy should be practised in the case of tumors for the purpose of diagnosis is mischievous and dangerous and should be contradicted at every opportunity.

Medico-Physics in the University of Lima.

This institution has a chair in medico-physics, of which Professor Mayorza is the incumbent. A program of the course appears in the *Anales de la Facultad de Medicina* for March-April, and includes the following subjects: Architecture of the bones, joints, etc.; height, volume, density, superficies, weight, etc., of the body; center of gravity; attitudes of the body; graphics; gaits; locomotion; cohesion, tenacity, and elasticity of the tissues; dynamometry; hydrostatics of the body; hydrodynamics; air pressures; animal heat; calorimetry; electrophysics of the body; *x*-rays; optics; acoustics; meteorology. Such a course might with advantage be taught in all medical schools, if time permitted, and it is much to the credit of the University of Lima to have inaugurated it.

News of the Week.

Influenza Still on the Increase.—Reports to the Public Health Service on October 18 showed that influenza was still on the increase in most parts of the country. The epidemic is more pronounced in the Eastern section than west of the Mississippi River. Up to October 16, New Jersey had reported 107,839 cases, with 2,232 deaths. The number of deaths reported in Pennsylvania up to October 15 was 10,046. Fewer cases are being reported from Massachusetts, but in other New England States the disease is still epidemic. In the District of Columbia the epidemic continues unabated. In Greater New York, the number of cases reported has continued to increase. On October 23 there were 5,390 cases reported. The hospitals are filled to overflowing with influenza patients, the surgical wards in some hospitals having been given over to this class of patients. The shortage of nurses is acute. A comparison of the statistics of the Health Department for the epidemic of 1889 with those of the present outbreak show that in proportion to the population more persons suffered from the disease then than during the present epidemic. Figures corrected to correspond with increased population show that during the first week of the 1889 epidemic there were 688 cases, as against 202 during the first week of the epidemic of 1918; during the second week, in 1889, there were 1,518 cases, as compared with 740 during the second week of the present epidemic; during the third week, in 1889, there were 2,180 cases, as against 1,972 during the third week of the epidemic of 1918. Admiral Usher, commandant of the Brooklyn Navy Yard, has forbidden the men of the Navy to ride in the subways of the city. The Polyclinic Hospital, which was to have been taken over by the Army this week, is being used by the Health Department for the care of influenza patients; and the New York Infirmary for Women and Children, as well as vacant houses and other buildings, are being utilized for the same purpose. Health Commissioner Robertson of Chicago, where the epidemic has not yet reached its height, has ordered the inoculation of every person in that city with vaccine. The public schools will be used for vaccination, and it is planned to vaccinate 100,000 persons daily. In New York City the Health Commissioner's Emergency Advisory Committee has announced the opening of forty-two centers in different neighborhoods where inoculations of preventive vaccine will be given and where all cases needing the care of physicians, nurses, domestic help, shelter, or food, should be reported.

Influenza in Other Countries.—An epidemic of influenza is ravaging the coast of West Africa. In Sierra Leone the deaths are said to average 1,000 a week. It is reported that the malady has spread to the interior and has attacked chimpanzees and monkeys, which are dying in numbers of the disease. A despatch from Kingston, Jamaica, states that influenza is epidemic in the West Indies, and is causing many deaths. Chili is also reported to be in the throes of an influenza epidemic. It is said that in some places near Santiago the deaths number three out of every ten cases. The epidemic has spread throughout the Dominion of Canada. A considerable number of cases are being reported from Quebec, Ontario, Winnipeg, Manitoba, and Vancouver.

Examination for Institutional Positions.—The Civil Service Commission of the State of New York announces that an examination will be held on November 9, 1918, to provide eligibles for the position of assistant physician in the State hospitals and other positions of a similar nature in various State and county institutions. The examination will be open to regular and homeopathic physicians licensed to practice medicine in this State. Applications must be in the hands of the Civil Service Commission at Albany by October 30.

Government Begins Fight on Tuberculosis Among Cattle.—The Federal Government has begun a nation-wide campaign for the eradication of tuberculosis among cattle, which it is estimated now costs the country $40,000,000 a year, besides endangering human life. The campaign is divided

into three well-defined projects. The first aims at the eradication of tuberculosis from individual herds of pure-bred cattle, the second at the eradication of the disease from the cattle in circumscribed areas, and the third to eliminate tuberculosis among swine in this country. It is estimated by officials in close touch that about 15 per cent. of pure-bred cattle in this country are affected with tuberculosis. For tuberculous cattle that must be slaughtered the Department of Agriculture is to pay one-third of the difference between the appraised value of the cattle and the salvage value, provided the State, county, or municipality in which the cattle are owned and kept is cooperating in the tuberculosis work, and pays at least an equal amount to the owner. It is believed that the provisions made for reimbursing cattle owners for slaughtered cattle will do much to remove the opposition that has hindered tuberculosis eradication work in the past.

New York Polyclinic Hospital Taken by Government.—An agreement has been reached whereby the Federal Government will assume control of the New York Polyclinic Hospital and Medical School.

Public Health of Porto Rico.—The first number of the new monthly health bulletin of Porto Rico, bearing the date July 1, has reached us. The estimated population of the island is 1,258,970. The number of births in July was 6282, over 2000 more than in July, 1917. The number of deaths during the same month, 3,246, is considerably below the total for July, 1917. The number of lepers in the colony is now 39. The number of patients in the two sanatoria for tuberculous subjects is 30. During July the number of individuals vaccinated was 4,352. The number of insane who are interned is now 469, the commitments for the month being 15 and the number released 8. The number of blind in public institutions is 81. The port of San Juan has rat inspection, and 811 rodents were examined in July. During the month 2,648 cases of anemia were treated by the State. Recently the Island suffered from a heavy earthquake by which much property was destroyed and many lives lost.

Removal.—Dr. Arthur A. Landsman of this city has removed his office from 17 East Thirty-eighth Street to 310 West Eighty-sixth Street.

Yellow Fever in Guatemala.—Cases of yellow fever are reported to have developed at San Jose, Guatemala, and the commandant and port doctors are said to have died from the disease.

The Medical Society of the Missouri Valley, at its thirty-first annual meeting at Omaha, September 19 and 20, elected the following officers: *President*, Dr. Charles Wood Fassett of St. Joseph, Mo.; *First Vice-President*, Dr. Watson of Diagonal, Iowa; *Second Vice-President*, Dr. J. M. Aikin of Omaha; *Secretary*, Dr. S. Grover Burnett of Kansas City; *Treasurer*, Dr. O. C. Gebhart of St. Joseph, Mo.

The First District Branch of the Medical Society of the State of New York, at its twelfth annual meeting, at Tuxedo, on October 17, elected the following officers for a term of two years: *President*, Dr. Joseph B. Hulett of Middletown; *First Vice-President*, Dr. George A. Leitner of Piermont; *Second Vice-President*, Dr. Edward C. Rushmore of Tuxedo; *Secretary*, Dr. Charles Ellery Denison of New York; *Treasurer*, Dr. John A. Card of Poughkeepsie.

Obituary Notes.—Dr. Walter Franklin Chappell of New York died suddenly at his residence in this city on October 19, aged 63 years. He was a graduate of the Toronto School of Medicine in 1879. Dr. Chappell was a Fellow of the American College of Surgeons, a member of the American Medical Association, the American Laryngological, Rhinological, and Otological Society, and the New York Academy of Medicine. He was surgeon to the Manhattan Eye, Ear and Throat Hospital and consulting laryngologist to the Loomis Sanatorium.

Dr. Charles Solomon Calverly, a graduate of the University of Vermont College of Medicine, in 1881, and president of the State Board of Health since 1891, died at his home in Rutland, Vt., on October 16, aged 62 years.

Dr. Thomas Nash Broaddus, a graduate of the Medical College of Virginia, Richmond, died of pneumonia at his home in Richmond, on October 5, aged 31 years.

Dr. Benjamin James Willingham, a graduate of the Medical College of Virginia, Richmond, in 1906, died of pneumonia following influenza, on October 5, aged 37 years.

Dr. Laura Stone, a graduate of the American Medical Missionary College, Chicago, in 1904, and a member of the staff of the Battle Creek Sanitarium, died of pneumonia in Atlanta, Ga., on October 3, aged 40 years.

Dr. William James Douglas, a graduate of the University and Bellevue Hospital Medical College, in 1908, died of pneumonia at his home in Belleville, N. J., on October 16, aged 34 years.

Dr. Alfred Friedman, a graduate of the College of Physicians and Surgeons, in 1876, died of pneumonia at his home in New York City on October 18, aged 67 years.

Dr. Harold Milne French, a graduate of the New York Homeopathic Medical College, in 1913, died of pneumonia at his home in Freeport, L. I., on October 18, aged 35 years.

Dr. Charles Ryttenberg of Port Chester, N. Y., died in a local hospital of influenza, on October 16, aged 36 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1906, a member of the National Association for the Study and Prevention of Tuberculosis, and of the American Medical Association.

Dr. Leonard Cassel McPhail, a graduate of New York University Medical College, in 1876, and consulting physician to the Brooklyn Orphan Asylum, died at his home in Brooklyn, N. Y., on October 16, aged 63 years.

Dr. I. Jacques Grossman, a graduate of the University and Bellevue Hospital Medical College, in 1915, died of pneumonia at his home in Brooklyn, on October 16, aged 27 years.

Edward Middleton Thompson of Brooklyn, N. Y., died of pneumonia at his home, on October 16, aged 41 years. He was a graduate of the University and Bellevue Hospital Medical College, in 1899, and visiting orthopedic surgeon to the Kings County Hospital.

Dr. Francis Joseph O'Neil, a member of the staff of St. Joseph's Hospital, Jersey City, died of pneumonia on October 11, aged 33 years.

EDWIN BRADFORD CRAGIN, M.D.

NEW YORK.

Dr. E. B. Cragin, whose death from pneumonia occurred on Tuesday of this week, was born in Colchester, Conn., on October 23, 1859, and was graduated in medicine from the College of Physicians and Surgeons (Columbia University) in 1886. After serving as interne at Roosevelt Hospital he entered upon practice in this city, giving his attention chiefly to the specialty in which he soon won fame. He was a member of the Medical Societies of the County and State of New York, the American Medical Association, the New York Obstetrical Society, and the American Gynecological Society, and a fellow of the New York Academy of Medicine and of the American College of Surgeons. He was professor of obstetrics and gynecology in Columbia University, attending obstetrician and gynecologist at the Sloane Hospital for Women, consulting obstetric surgeon to the New York Maternity and the Nursery and Child's Hospital, and consulting gynecologist to the Presbyterian, Roosevelt, and Lincoln hospitals, to the New York Infirmary for Women and Children, and to St. Luke's Hospital, Newburgh, N. Y. Dr. Cragin was the author of the "Essentials of Gynecology" and of a "Text-book of Obstetrics," and one of the contributors to the "American Text-book of Gynecology."

Correspondence.

LAY ANESTHETISTS.

To the Editor of the Medical Record:

Sir:—A gradually increasing misconception of the Art of Anesthesia has led to a rather unique condition of affairs.

We find that nurses and other lay persons may, by the simple acquisition of a few rules, become anesthetists. Large institutions have adopted the nurse anesthetist upon grounds of economy, expediency, and even sentimentality. It is argued that these workers can be employed at little expense, that the supply meets the demand and that the feminine element eliminates fear and works for smoothness during the induction of the anesthesia.

These institutions may employ lay persons to take their *x*-ray pictures and to make urinary, blood, or sputum examinations, but does any one dream of speaking of these workers as the hospital roentgenologists or the attending pathologists? They are employed as technicians and the nurse who administers an anesthetic is an anesthesia technician. She can never be more without a medical degree, for in order to understand the language of anesthesia one must have intimate acquaintance with anatomy, physiology, medicine, surgery, diagnosis, psychology, and special branches.

The nurse who in discussion with a medical man attempts to defend a theory relating to anesthesia cannot fail to feel the presumption of it and, if graced with wit, to see the absurdity of such a position. Yet it has actually come to pass that medical men have suffered themselves to be instructed by a nurse in the theory and practice of anesthesia.

In justice to an important branch of surgery and to our medical confrères who devote their training and their energy to its development, let us drop the term anesthetist as applied to its non-medical workers and adopt the term anesthetic technician.

Paluel J. Flagg, M.D.
War Demonstration Hospital of the Rockefeller Institute, New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE STREET-WALKER IN LONDON—AMERICAN RED CROSS HOSPITAL AT LIVERPOOL—DEATH OF CHARLES DEVEREUX MARSHALL—THE RAILWAY STRIKE—ROYAL AIR FORCE MEDICAL SERVICE.

London, September 26, 1918.

Mr. Edward Bok, editor of the *Philadelphia Ladies' Home Journal*, at present a guest of the British Government and engaged on a special mission, has sent to *The Times* a remarkable indictment of the condition of the London streets, which he describes as being, together with hotels and restaurants, the scene of huge and uncontrolled solicitation of soldiers by prostitutes. Mr. Edward Bok disclaims any discourtesy in his plain speaking while he is a guest, but this is entirely unnecessary, for his mission here is to cement in every possible way the relations between Great Britain and the United States, and the more plain speaking there is between the two countries, the firmer will be the resulting alliance. But those who know best do not consider his picture accurate. Mr. Bok speaks of the temptation offered to "our soldiers, clean-blooded and strong-limbed over here only to be poisoned and wrecked in the London streets," and goes on to demand that the streets should be swept of prostitutes, that the houses of ill-fame should be closed, and that strong government action should be taken. Now, medical men know full well the prevalence of venereal disease in London, and among the soldiers, but those who live in London know perfectly well also that never has the street life of this huge city, in the recollection of living men, been more decent. It is undoubted that a large number of the girls whom Mr. Bok has mistaken for prostitutes are happy-go-lucky wage-earners, possibly with no high moral standard, but as far divided from prostitutes as from vestals. There are prostitutes in London streets, and those who look for them can easily find them, for their centers of congregation are matters of common knowledge; but even at those centers no man will be solicited if he does not to some extent invite the offence, while solicitation is an illegal offence, though one which is difficult to prove. The suggestion that the streets should be cleansed of all prostitutes, coupled with the remark that houses of ill fame should be closed, is doubly confusing. It is obvious that such prostitution as cannot be eliminated by legal methods, if driven off the streets will tend to secrete itself in houses, but it appears to be unknown to Mr. Bok that there are no "houses of ill-fame" or "red lamp houses" or "great number houses" in London. For many years now the presence of two or more women in one house, who are known to be living on the earnings of prostitution has laid the owner of the house open to prosecution. In less

regenerate times, when public women had taken over certain streets in London, the premises and the inmates were subject to no government inspection, so that if by strong government action Mr. Bok meant an inspection of brothels, he is asking for a new Act of Parliament to regulate the proceedings of non-existent establishments. Mr. William C. Edgar, the editor of the *Bellman*, Minneapolis, writing to *The Times* with obvious and intimate knowledge of London life, apologetically describes Mr. Bok's fulminations as "hogwash," saying, "I have been visiting London at intervals for nearly thirty years, and in all my experience I have never found its street life so free from all objectionable features of the kind"; and it is an excellent thing that Mr. Edgar's independent reply should have followed so promptly upon Mr. Bok's honest but mistaken indictment. For undoubtedly these lurid charges against the morality and decency of London life give terrible pain to many men and women, the parents, relatives and *fiancés* of the soldiers. Into the huge maelstrom of London a large proportion of the Allied armies find their way now and again; it is little less than a tragedy that their home circles should be asked to believe that they are almost perforce driven to dangerous vice.

As a matter of fact, it is not the women who do (or who do not) solicit at street corners, in the "lounges" of public houses, in so-called "tea-rooms," and in the lobbies of cinema shows, who cause the medical profession any great anxiety. The number of these women is comparatively small, and they have a knowledge of preventive hygiene which to a considerable extent minimizes the perils arising from the promiscuity of their embraces. The real danger to the soldiers, as well as to all the womenfolk of the country, lies mainly in the irregular actions of girls who do not strictly speaking solicit, who do not strictly ply a professional calling, but who surrender themselves, more or less accidentally, to a chosen man, while their standards of morality and powers of self-control are insufficient to prevent them from entering into relations with another man as soon as the first one has disappeared off the scene. These girls, only half vicious, quite ignorant, and usually acting without the knowledge of their friends or their employers, contract and spread gonorrhea, and in so doing are a real threat to the future of the race. These are the people whom the National Council for Combating Venereal Diseases are vainly striving to reform. The prevalence of venereal disease and especially of gonorrhœa in the British army both at home and abroad, though no longer the source of real apprehension that it was some two years ago, is none the less a drain upon manpower of a sort that ought to be prevented. The National Council has done real good, and the foundation of venereal clinics has provided centres at which sufferers can obtain prompt care. There are medical men in attendance at these centres, who learn the clinical practice of experts and deal with cases by the modern methods. These methods are effective for males, who are by an enormous majority the attendants at the clinics, but chronic gonorrhea in a woman is almost an incurable disease and the most fruitful source of sterility. The greatest danger of gonorrhea lies in the future, when many potential mothers are found incapable of procreation.

The American Red Cross Hospital at Liverpool was opened in January last with 75 beds at Mossley House, the property of Mr. Edmund Muspratt, vice-chairman of the United Alkali Company. Almost immediately the premises were extended to accommodate 200 patients; by April it was again reconstructed to hold 500 patients, and just now it has been equipped by Captain M. W. Leonard so that it can receive yet another 300. In six months the hospital has grown from 3 medical officers and 12 nurses to a personnel of over 200, including 18 medical officers and 60 nurses.

The death has occurred at Colaba Hospital, Bombay, one of the war hospitals of the Navy in the East, of Staff Surgeon Charles Devereaux Marshall, principal medical officer with the Persian Gulf and Mesopotamian expeditionary forces. Staff Surgeon Marshall succumbed to cholera the day before yesterday (Sept. 24) and his loss to the men under his charge can hardly be exaggerated, so capable and popular was he. He was an officer of the Royal Naval Volunteer Force of some years' standing when war broke out, and joined up at once in the ordinary conditions of his service. He was almost immediately promoted, and saw service in home waters and the Mediterranean before proceeding to the important appointment which he held at the time of his death. A very competent surgeon, and skillful operator, Marshall had been a well-known ophthalmic surgeon in civil life, and surgeon to the Royal London Ophthalmic Hospital (Moorfields) and ophthalmic surgeon to the Victoria Hospital for Children (Chelsea). The author of many papers on ophthalmic subjects, he had written an excellent treatise on diseases of the eye, and also made important contributions to the subject of color-blindness. He was just 50 years of age at his death.

A railway strike broke out at the beginning of this week, but fortunately collapsed just as it bade fair to become general. Medical men in charge of wounded soldiers at distant and isolated spots were considerably embarrassed, while the temporary shortage in London of milk and vegetables had begun to be felt seriously in hospitals, and by invalids and babies. As the strikers were roundly told by a unanimous press, their action was equivalent to a German victory.

The Royal Air Force Medical Service came into being as a separate entity over a year ago, and its parturition was a distinctly stormy act. At that time the Air Force, half a naval and half a military arm, had attached to it medical officers mainly of the Royal Army Medical Corps, and it is no discredit to those officers to say that they had no particular conception of what the duties would be in ministering medically to the needs of flying men. The flying man was not at first selected for any particular qualifications—speaking generally—he was young and brave, and if he was up to a certain physical standard he was allowed to enter upon his training. Similarly, when once a flying officer the trials of the new life as they affected

his cardiac or respiratory systems attracted no especial attention, nor did it occur to anybody that the officer who was the victim of an accident, might have incurred that accident through some physical default, which if it had been detected could either have been remedied or have been used as a proper excuse for stopping further aviation on his part. As in the course of the war aviation began to shape itself as an arm of offence and defence which is the complement of the navy and the army, the necessity and humanity became evident of economizing in the material, first by selecting as flying officers only those who were likely to prove good at the work and secondly by caring well for such officers when selected. Obvious as this must be, it was left to medical men to point out to the authorities and to urge that the Air Force ought to have at its disposal highly qualified medical officers, and ought not to be dependent on the medical service of either the army or the navy. There was grave resistance in bureaucratic circles to the creation of a new service while the war was on us—and doubtless we had in those same circles persons who objected to the manufacture and employment of tanks because there had been no tanks before the war. There was a time when the opposition to a really scientific medical establishment in connection with the Air Force made it seem impossible of realization, but in the end the Force obtained its separate medical service, although the conditions under which the medical officers were to work remained indefinite. Now those conditions have been published, and they are at once seen to form an advance upon the terms offered to medical men either in the army or navy. The advance is not so much in money, or indeed at all in money; it is constituted entirely by the scientific spirit which inspires the circumstances in which medical officers of the Royal Air Force will work. The scope of the service is divided roughly into two main divisions, namely (1), care of the effective personnel and (2) care of the non-effective, whether by sickness, disability, or accident. The former may be considered to represent the hygienic and preventive side of the work, and to include such special subjects as selection and care of the flying personnel, maintenance and improvement of the physical efficiency of all ranks, sanitation, etc. The latter represents the curative side of the work. Here certain subdivisions, which facts have already shown to be necessary in the care of aviators, will be recognized, namely, neurology, surgery of the eye, throat, nose, and ear, and plastic surgery, while general medicine and pathology will be undertaken by men of broad experience. Under this system it will be possible to allocate each medical officer of the Air Force to the work that suits him best. For selecting good flying officers a knowledge of men and manners will be a great asset. The doctor who has been at a public school and a university and who has lived in communion with young sporting men, will know many things that will assist him in chosing the best flying officer; on the other hand, all the different branches of therapeutics, medical as well as surgical, will fall into appropriate hands. The deadly trouble of regimental routine is thus avoided, namely, that scientific men, with the unquestioned spirit demanded of all officers, go off unprotestingly to do what they cannot do, and further go off knowing that by the time they have learned to do the work they will be promoted to something quite different. Moreover, in the Medical Service of the Royal Air Force promotion is by merit and not seniority, so that the medical officer, if the scheme works as it is intended to work, will not only find himself employed upon congenial tasks, but will be rewarded if his efforts are particularly good. With such incentives it will be surprising if the service does not hold out many inducements to young men for employment.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

REMOVAL OF FOREIGN BODY FROM THE LEFT VENTRICLE—CARDIAC HYPERTROPHY IN AVIATORS—HOSPITALS THE SIZE OF CITIES—MRS. COREY DONATES CHATEAU TO THE RED CROSS.

PARIS, September 3, 1918.

AT a recent meeting of the Paris Academy of Medicine Dr. René Lefort presented a wounded soldier from whom the 13th of June last he removed a fragment of a hand grenade from the left ventricle. The operation was perfectly successful, the hemorrhage was limited to two jets of blood and the respiration was arrested momentarily during the incision of the ventricle. The fragment had rested nine months in the cavity. This is the first recorded case of the extraction of a projectile from the left ventricle. This makes nine operations upon the heart made by Dr. Lefort, seven for foreign bodies in the heart wall and two intraventricular, one of which succumbed the fourth day after the intervention.

Drs. Etienne and Lamy presented a report of a series of examinations of the heart of aviators. Without exception there was a degree of hypertrophy after five months' flying, persistent still after eight months' repose from their professional work. The hypertrophy was confined to the left ventricle. No case presented where the cardiac change was not seemingly well tolerated, the hypertrophy did not seem to interfere with the physiological function of the organ and was caused by the effort of the heart to adapt and protect itself against the vascular tension determined by the rapid atmospheric changes and quickly recurring mental excitement incident to the varying altitude and necessities of combat.

Base Hospital No. 38 represents the Philadelphia Jefferson unit, and the medical staff is under Colonel J. S. Lambie, of Jefferson Medical School. There are over thirty doctors in this hospital, and their services are distributed among 300 patients, which means that this contingent gets mighty good care. However, there is room for 3.000 patients, while in time of pressure, 3,000 more can be accommodated. Added to this there is a convalescent camp for 2,000 men, which brings up the total to 8,000.

In the same town is Base Hospital No. 34, over which Colonel Devoe presides. The colonel is from the University of Pennsylvania. This hos-

pital resembles the American Hospital at Neuilly, inasmuch as it is a new seminary taken over for the American wounded. Everything here is spick and span. It was opened in January, but patients did not come until three months afterward. The colonel thinks it more suitable for hospital purposes than most places taken over for the army. He says the entire building, with annexes, is wonderfully well arranged, and such details as the sewage are of the best modern arrangements. There is accommodation here for 1,300 patients. Most of the medical staff of eighteen doctors come from Philadelphia, being connected with the Episcopal Hospital there. It is a general hospital and not limited to special cases.

At a place near there is another hospital getting into shape. It will accommodate from 12,000 to 15,000 patients. Then there is another enormous hospital in an adjoining town where patients are received from the first-mentioned hospitals. If the wounded men are found to be incurable, or if the chances are that they will not be of use at the front again, they are sent back home to America.

The enormous hospital accommodation for American troops in France is very ingenious. As wounded men come from the front they may pass through quite a number of hospitals. They go gradually from the front toward one of the hospital ports where the accommodation is very great. The nearer they get to the sea the better they are likely to become so that they soon are able to return to the front again, or if they show no prospect of quick recovery they are sent back home.

Mrs. William E. Corey has handed over the Château de Villegénis, Massy, Seine et Oise, to the American Red Cross for a convalescent home, to be known as the "Corey Home." The formal opening will take place to-day. The estate is princely —there is no other word for it. Laid out for Jerome Bonaparte, it comprises about 200 acres of beautiful land. Traversed by the Vièvre, and wooded with about 50 acres of forest land, it comprises a babbling brook, two lakes, one of which contains an abundance of fish, 40 acres in crops of wheat, oats, and barley, and 30 acres of hay land, a large swimming pool (2 meters deep), orchard, vegetable gardens and flower gardens— where convalescents will have the time of their lives when assigned to that fair corner of France.

The rose gardens are two in number. One of these rose gardens is a covered vault, 200 yards long and thickly festooned with roses. The other is nearly as long. There are stables for fifteen horses and automobile garages for four machines. Long avenues of ash, oak, and elms invite health-giving promenades among stately trees that throw their cooling shades over the walks, making hot weather not only tolerable but delightful. The Château de Villegénis can be approached by train or auto, and soon the termini of the newly constructed railway line from Paris will be available. Probably few estates exist with such enormous advantages as health resorts and what its future may be can easily be imagined, as the surrounding district is exceptionally beautiful.

146, Avenue des Champs Elysées.

CANADIAN LETTER.

(From an Occasional Correspondent.)

PUBLIC HEALTH AND FOOD CONSERVATION—THE MEDICAL PROFESSION OF ONTARIO AND PROHIBITION— INFLUENZA IN EASTERN CANADA—DR. H. B. ANDERSON APPOINTED REFEREE—OFFICERS OF THE ONTARIO MEDICAL COUNCIL AND OF THE MEDICAL COUNCIL OF CANADA—PERSONAL NOTES.

Toronto, October 5, 1918.

An interesting and a useful feature of the Canadian National Annual Exhibition, recently held in Toronto, was the exhibit of the Ontario Board of Health. By means of moving models the menace of the fly, the facility with which a rural water supply may be contaminated, the dangers involved in the use of the common drinking cup, and the results of effective and of improper ventilation of sleeping apartments were illustrated. The necessity for the prevention of communicable diseases was emphasized by an exhibition of the various biological products which the board is supplying to the public of Ontario free of charge.

The question of tuberculosis was fully dealt with, being allotted a special section. Posters were displayed which bore upon the general aspects of the problem. Ten of these were devoted to a consideration of the prevalence of the malady in childhood. Venereal diseases received very particular attention, the object being to instruct the public. By the aid of excellent charts the outstanding facts in connection with the disease were graphically brought out, while available statistics were introduced to clinch the argument and to dispel some of the ignorance with which the subject of the venereal diseases is still shrouded so far as the general public is concerned.

Special stress was placed upon child welfare at the exhibition. By a system of free clinics, expert medical and dental advice was made available to mothers of infants and of children up to sixteen years of age. These clinics were in operation from two o'clock up to five o'clock during the time the exhibition was open. A rest room for nursing mothers was provided. Qualified trained nurses were in charge throughout the day and evening, and practical demonstrations in the care of the baby, under the headings of bathing, clothing, and feeding, were given every afternoon. As the primary object of the exhibit was to stimulate interest in infant welfare work and medical and dental inspection in the schools, clinics for these purposes were held daily. The equipment used by the Department of Public Health of the city of Toronto was lent for the occasion, as well as the services of the medical staffs of the various divisions. The Public Health Board of Toronto heartily cooperated with the Ontario board, and it is to this practical appreciation that their interests were identical that the unqualified success of the exhibit was due.

Another feature of the exhibition closely related to the public health and to the successful prosecution of the war was the department dealing with food conservation. The various methods for conserving food were fully demonstrated, but the only one to which attention will be drawn here is a new process devised and introduced by Dr. W. B. McLaughlin of New York. Dehydration of certain

foodstuffs, principally vegetables, by the latest methods, by means of moderate heat and air currents, appears to have answered the purpose in a satisfactory manner. By some, however, it is claimed that dehydration pure and simple materially injures the flavor of vegetables, and, moreover, the adding to them of their proper quota of water is a somewhat tedious process. It is said that the process brought out by Dr. McLaughlin embodies the best features of dehydration and canning, and avoids their main defects. The principle of this method is that fruits and vegetables are only partially dehydrated, the result being that the housewife may easily restore the food to its original state or to the necessary state of rehydration. It is urged on behalf of this method that the great loss of time experienced in using dried fruits is saved, and that owing to the moisture retained after partial dehydration the flavor of the products is preserved. The weight is reduced according to the degree of dehydration, and varying with the amount of the original moisture, from one-fourth to one-third the weight of the product in the normal state. This affords a consequent decrease of bulk, with all which that signifies in containers, shipping, storage, carting, and other costs. After the products have been partially dehydrated they are sterilized by placing them in a vacuum chamber and then admitting live steam for a period of from six to ten minutes. The heat employed by this mode of sterilization is considerable. It is said that steam at 250° F. has been found satisfactory, and that owing to the short period required for sterilization as compared to the canning process there is far less cooking or breaking up of the tissues of the products, thus leaving the foods in a more attractive condition. After undergoing the sterilization process the foods are put up in tin or glass receptacles.

Since prohibition has come into vogue in Ontario it goes without saying that in order to obtain alcohol many subterfuges have been resorted to by those who have become habituated or addicted to its use. Those desirous of providing themselves with their customary stimulants without laying themselves open to the rigors of the law, adopted the plan so well known in other communities of applying to a medical man for a prescription ordering alcohol in some form as a medicine. One or two physicians have been prosecuted for the freedom with which they have given prescriptions for alcohol. Complete returns from all the vendors of alcohol in Ontario, issued recently by the Ontario License Board, show that during August last over 90 per cent. of the medical men in the province gave out not more than twenty-five prescriptions, their average being 5.26 per medical man. Five per cent. of the profession issued more than twenty-five, but less than fifty. It would appear that these physicians gave more liquor prescriptions than the therapeutic indications in their practice justified. The others were offenders against the Ontario temperance act, the average of their prescriptions for alcohol during the month being 124.79. According to the lay journals, the difficulty of securing conviction in cases in which the medical man flagrantly and patently contravenes the law is likely to result in a change in the Ontario temperature act at the next session of the Legislature. In adopting the clause permitting physicians to issue prescriptions for liquor the Legislature assumed that the medical profession would scrupulously comply with the strict spirit of the law. As the law now stands, the medical man who is prepared to testify that in his judgment the applicant needed liquor as a therapeutic measure will go scot free. It is somewhat difficult to understand how the law will be altered so that it will not be left to the discretion of the medical man to prescribe alcohol. As long as alcohol is regarded as a drug it will be infringing upon the rights of the profession to prohibit its prescription as a medicine. On the other hand, when a doctor writes in one month 725 prescriptions for alcohol, as the returns of the Ontario License Board show that a practitioner in Ontario did, it would seem that prohibitive steps should be taken.

While it can hardly be said that influenza is rife in Canada, it is prevalent in certain parts of the Dominion. There are many cases of the disease in Montreal, and it is reported to have broken out in epidemic form in barracks there. The Khaki League Convalescent Home has been set aside as a hospital to deal with influenza cases. In the Polish army stationed at the Niagara Camp, Ontario, influenza has been present for some little time. There are now about 160 cases in hospital, and there have been ten deaths.

Dr. H. B. Anderson has been appointed by the Minister of Education chief medical referee for the Ontario branch of the Inspectors and Teachers' Superannuation Fund Commission.

The annual meeting of the Ontario Medical Council was held from June 25 to June 27. The officers elected were: *President*, Dr. R. Ferguson; *Vice-President*, Dr. A. T. Emmerson; *Registrar-Treasurer*, Dr. H. Wilberforce Aikins; *Solicitor*, H. S. Osler, Esq.

The Medical Council of Canada, at the concluding session of its annual meeting, at Ottawa, elected the following officers for the current year: *Honorary President*, Sir T. G. Roddick, Montreal (reelected); *President*, Dr. R. Eden Walker, New Westminster; *Vice-President*, Dr. I. C. Connell, Kingston; *Registrar*, Dr. R. W. Powell, Ottawa (reelected); *General Counsel*, F. H. Chrysler, K. C., Ottawa; *Auditor*, G. L. Blatch, K. C., Ottawa.

Dr. F. N. G. Starr, a well-known surgeon of Toronto, who has recently joined the R. A. M. C., has arrived in England. He has been appointed a consulting surgeon to the Canadian forces in France. Col. A. E. Ross, M. P. for Kingston, has been appointed director of medical services for the Canadian Section, general headquarters in France.

9. Improving the Sight of Soldiers and Sailors. W. H. Bates.

8. The Real Value of Fresh Air in Tuberculosis and Many Infectious Diseases.—Charles Gluck believes that the whole domain of the treatment and cure of diseases will be revised by the work now being done by the nose and throat specialists, whose view is more mechanical and therefore more efficient and practical. Germs themselves cannot produce disease; the predisposing factors must be present. The first of these are with us all, such as the strain and stress of life, worry and exposure, but the second—the nasopharyngeal factors—are the only means whereby germs accomplish their work. Gluck points out that the production of disease is chemico-mechanical, and he lays particular stress on the mechanical side. Inspired air which is drawn through abnormal or diseased nasal fossæ or the mouth results in suboxidation, facilitates the growth of germ life, especially in the nose and throat, and leads to disease. In illustration of the fact that abnormalities of the nasopharynx produce or aggravate disease, the case of interstitial keratitis is quoted, which in a child with perforated or deflected septum, enlarged tonsils and adenoids is difficult to cure, but which clears up under simple treatment in a ehild with normal nasopharynges. Air which is breathed by mouth or drawn through abnormal nasal fossæ is not properly moistened, warmed or filtered, and gives rise to a condition of the body tissues which permits of germ growth and infection, the natural resistance thus being lowered. Not only is it important that sufficient air should be drawn into the lungs, but a sufficient quantity must be absorbed into the system by the lung alveoli if health is to be maintained. The body should be regarded as a machine which cannot work properly unless the mechanical factors are right. The three cardinal points of a deranged nose and throat are: The presence of diseased tonsils; tissues found in the pharyngeal vault, consisting of adenoids or their remains, and adhesion bands; the deflected nasal septum. In a child the more the tonsils and adenoids are infected, the more they swell; and the greater the swelling, the greater is the interference with normal nasal breathing. The more the child breathes with its mouth, the greater is the degree of suboxidation and the more will germs proliferate and be absorbed. Thus a vicious circle is established which results in colds, and later in pneumonia, diphtheria, and tuberculosis. That this is so is demonstrated by the fact that if the faucial tonsils are completely removed and the vault of the pharynx thoroughly cleaned out, the child grows and is free of almost all ailments. In eczematous keratoconjunctivitis and all infiltrative inflammatory disease of the cornea, both faucial tonsils should be enucleated and every vestige of adenoid tissue and adhesion bands taken from the pharyngeal vault, which subsequently should be scraped by the index finger at intervals of three, six, and nine months after operation (this is essential in all eczematous children). A complete submucous operation should also be done in all cases that require it. The finger snare method for complete enucleation of tonsils under local anesthesia (novocaine) is the best. In the adult the disease producing mechanism is the same, but of the three cardinal points mentioned the third is perhaps the most important. All other abnormalities of the nasal fossæ are secondary to the deflected septum, diseased tonsils and vault abnormalities. In older people adenoids are usually atrophied, leaving bands of connective tissue which stretch between the vault of the pharynx and the pharyngeal projecting ends of the Eustachian tubes, and it is in the interspaces between these bands that the germs breed. Gluck believes that tuberculosis in all its forms can be prevented and eradicated by the means indicated, and that we possess a wonderful instrument for the prevention of many other ailments and the more scientific treatment of disease when present. The reason for breakdowns may be more easily understood and an explanation furnished for cases of malnutrition, underweight, anemia and so on. All such conditions, he believes, may be successfully treated by destruction or removal of the disease producing mechanism described; and this can be done in the manner indicated. He states that no tuberculous patient is properly treated unless his tonsils are completely removed, and he is assured that in his nasal fossæ there exists a straight and thin nasal septum, and that he possesses a perfectly clear pharyngeal vault, a fact to be repeatedly ascertained. This means a complete submucous operation on the nasal septum in every tuberculous adult who is able to stand the operation. Such a procedure can only be adopted under the most careful scientific handling as regards diet and rest in bed, or absence from work. Cases of other infectious diseases may be given ambulatory treatment. It is seldom necessary to remove much turbinate tissue; a little trimming of the edges of the middle turbinate on the concave side of the septum will be necessary, to reduce it to normal size. This is true also of the inferior turbinates. Polypoid tissue must be removed but the necessity of sparing as much of the turbinate tissue as possible must be borne in mind.

7. The Bacteriology of Measles.—Ludvig Hektoen reviews the literature on this subject and concludes that the chief bacteria to engage the attention in connection with measles at present are: (1) the diplococcus found by Tunnicliff in the blood early in the attack and in the throat and nose; (2) influenza bacilli, and (3) hemolytic streptococci. As opsonins and probably other bodies specific for the Tunnicliff diplococcus come into the blood in the course of the measles attack, this coccus must be of some significance, but the exact significance we have still to learn. While hemolytic streptococci seem to predominate overwhelmingly in the bronchopneumonia and other allied acute processes in measles, influenza bacilli are found so frequently in the throat secretions and in lung lesions that doubt arises as to their harmlessness. Hence the part played by these bacilli in measles should be studied further. As hemolytic streptococci may spread rapidly among measles patients, and largely it would seem by droplet and throat infection, in order to avoid the most serious complication of measles, that is, streptococcus bronchopneumonia, the patient should be isolated under conditions that protect against infection from persons, including fellow patients, who may harbor streptococci. Such isolation also protects against other infections (pneumococcus, influenza bacillus). The possible danger of streptococcus infection by way of food should not be overlooked. Finally, it is evident that the immunology of the streptococci concerned, their unity or plurality, their changes in virulence, and other problems require continued investigation.

2. Preliminary Note on the Association of Rickettsia Bodies in Lice with Trench Fever.—J. A. Arkwright, A. Bacot, and F. Martin conclude from their observations that: (1) The constant presence, after a suitable lapse of time, of rickettsia bodies in lice which have been fed on a trench fever patient has been confirmed. (2) The absence of rickettsia bodies from lice bred in captivity and fed only on healthy men has been shown by their work, in contradistinction to observations made on the Continent, where the population is much more exposed to infection and a clean stock of lice is more difficult to procure than in England. (3) A very close correlation has been shown to exist between the presence of rickettsia bodies in lice or the excreta of lice and the virulence of these materials when inoculated into men.

6. Boot Heels as a Cause of Flat-foot, Soldier's Heart, Myalgia, Etc.—Captain Sylvester D. Fairweather points out that to cure flat foot the heel and sole should be of the same thickness. Arch supports and thickening the inner side of sole and heel fail to cure because the os calcis is raised from the ground, with the result that the weight of the body falls on the arch instead of the heel and outer side of the foot, and consequently the peroneus longus and brevis, while extending the foot, also evert it, and the tibialis anticus becomes elongated and no longer supports the arch. Boot heels rob the arch of its elasticity instead of supporting it. Exercises should therefore aim at developing the tibialis anticus, and not the calf muscles as hitherto taught. A heel even a quarter of an inch thick is harmful. He also points out that flat-foot is no disability if heelless boots are worn, except in hopeless cases; that boot heels help to produce soldier's heart, myalgia, and numerous other ailments, and that with heelless boots women would not require corsets.

June, 1918.

Two Cases of Adrenal Insufficiency.—Betchov and Demole relate the following cases: Man, aged 44, had recently gone through an attack of quinsy, after which he suffered from what was regarded as lumbago. The next symptoms were those of probable malignant disease of the left side of the neck—a parent lesion and enlarged regional lymphnodes. He also began to emaciate without apparent cause, which reinforced the diagnosis of malignancy. It was thought that the tumor in the neck was a secondary nodule, but no primary growth could be detected anywhere. The remainder of the finds of a systematic examination were also negative with the exception of vascular hypotension. This first drew attention to the adrenals and Sergent's white line was repeatedly obtained. Poultices applied to the loins brought out a brown pigmentation. An injection of adrenaline increased the blood pressure without causing glycosuria. The lumbalgia had persisted. The patient was interned technically for a slight bronchitis, but in the hospital he rapidly sank and died of adynamia. Autopsy revealed a complication of affections, the primary growth being an ulcer of the base of the tongue with numerous metastases, including the visible ones of the neck. The right adrenal was the seat of a cancerous metastasis, while its fellow appeared to be hypertrophied. The second patient was a man of 24 years, who went through a typhoid fever complicated with perforation and peritonitis. Owing to the profound state of depression, a surgical operation was out of the question. The presence of the white line and low bloodpressure showed the condition of the adrenal functions. Death was preceded by the development of acute hemorrhagic diathesis. There was a marked anatomical foundation for the adrenal insufficiency, but the lesions could not be interpreted beyond evidences of degeneration of some sort. Such lesions have frequently been encountered in death from acute infectious diseases, but the rationale is not apparent, although the adrenals have evidently lost most of their lipoid content.

The Regeneration of Joints.—E. Payr, in this final instalment of his article, again insists on the part played by the muscle functions in the re-establishment of the physiological articular play. Regeneration of a joint is, all things being equal, the function of the simplicity of the mechanical arrangement. Thus, in the case of the elbow, flexion and extension return more rapidly and completely than pronation and supination. Besides the part played by muscular movement, passive movements play an appreciable part in re-establishing functional activity. For that matter, this may be entirely independent of a return to the former state of the joint and radiography often reveals the most grotesque joint deformities, although the articular functions are perfect. Rest, which is unquestionably an excellent therapeutic measure, is generally employed to the point of exaggeration by most surgeons; therefore, contraction of the synocial membrane, processes of retraction of the fibrous capsule and ligaments, bone atrophy, and muscular contraction ensue. Permanent immobility is the outcome of too long rest and is due to extra-articular changes much more than to anhylosis. Anhylosis brings the writer to the question of arthroplastic operations by violent disjunction, bone modeling and interposition of various forms of tissue flaps. A well applied extension assures proper gaping of the joint cavity during the process of repair. The writer has been able to examine cases a long time after discharge from hospital and he found in place of the interarticular line a membranous connective-hyaline-sclerous network, without any trace of chondrification, enclosing some small clefts with mucous contents, in its meshes. In closing, Payr refers to the importance of the study of the normal development of joints in order to understand the phenomena of regeneration.

The Treatment of Infected Gunshot Wounds with a 10 Per Cent. Sea Salt Solution.—C. Stieder argues in favor of the treatment by sea-salt solution, which he considers superior to Dakin's fluid.

Münchener medizinische Wochenschrift.

August 6, 1918.

A New Procedure of Surgical Experimentation.—E. Sehrt has applied to the internal viscera direct observation of the capillaries as Müller has inaugurated it in the case of the skin. The small intestine of animals may be examined *in vivo*, the circulation being distinctly visible with the changes it may offer from pathologic causes. Thus, ligature of a portion of the mesentary immediately causes a special aspect of the capillaries of the gut, namely, a dilatation and immobility of the vessels. The writer has made the important observation that the area involved extends much beyond the zone actually involved by the mesenteric ligature, this latter including 32 centimeters while the circulation ceased over an extent of 28 centimeters above the ligated area. When the animal was killed the intestinal necrosis was, in reality, about 70 centimeters in extent. Sehrt's procedure would thus seem to allow one to judge the viability of a given portion of the intestine and the writer proposes to continue his studies on other organs, as, for example, the brain.

Meinicke's Reaction in Syphilis.—F. Lesser points out that the union of the antigen with the antibody has not been demonstrated by complement deviation, but rather by the presence (or absence) of a persistent occulation when in presence of a Na Cl solution. This reaction has been experimented with by Lesser, who declares himself convinced of its great value. The comparative tests with the classic Wassermann offers a satisfactoy concordance. Although Meinicke's method is much more simple than Wassermann's it should not, however, be considered as more available, and although it is true that all animals are eliminated in the procedure, it nevertheless requires minute technical precautions, as well as reactions in series, according to the plan given by Lesser in the text. The reaction is not applicable to the cerebrospinal fluid.

The Clinical Aspects of Typhus Fever.—E. Nobel and J. Zilczer have followed epidemics of this disease in prisoners' camps. The most rapidly progressive epidemic that the writers met with was quickly checked by hygienic measures, particularly the destruction of lice. In typhus foci in the country flying columns equipped with necessary disinfecting apparatus have been able to clean up a radius of 45 kilometers at a time. Isolation of suspected cases shows that incubation may last as much as twenty days. The disease seems to present exacerbations during cold weather, this being perhaps due to great promiscuity among the men. The disease usually offers a gravity in direct ratio to the age of the patient. The mortality which is 5 per cent. up to the age of fifty years, reaches 30 per cent., 60 per cent., and 100 per cent. in patients between seventy to eighty years of age. Among the complications the writers mention pneumonia, nephritis, bilateral parotiditides and especially mental disturbances.

July 18, 1918.

Antianaphylactic Treatment of Various Affections.—Danysz discusses the possibility of a general plan of antianaphylactic treatment applicable to asthma, various dermatoses and certain gastrointestinal disorders. Plenty of work has been done along special lines but without attempts at coordination, although Besredka, the leading authority on antianaphylaxis, has pointed out numerous analogies. The author differs from any of his colleagues in seeing a basic resemblance between subjects at the first sight quite unrelated, this bond of union being none other than what is known as antianaphylaxis. In fact almost the whole of biological therapeutics may plausibly be brought under this rubric. The author believes that the sensitizing agents to various affections may preexist in the subject's own tissues, and cites the case of an asthmatic whom he cured by making a sterile culture from his intestinal flora. The control of the paroxysms by hypodermics was remarkable. After two series of ten injections each the patient appeared to be immune to his own poisons. The treatment was confirmed on cases of skin disease. A trial of the remedy by the mouth in a single instance seemed to be without effect. The author sums up his views as follows; any microorganism or foreign protein when swallowed can behave as an antigen and can sensitize the organism with the production of certain disease pictures. The neutralization of these antigens by vaccines, serums, etc., is fundamentally the same process as when these methods are exhibited against extraneous bacteria and toxic products.

Finska Läkaresällskapets Handlingar.

February, 1918.

Malaria in Abo.—Ekholm discusses the subject of the incidence of malarial fever in the city of Abo during the period 1881-1916. Records exist which show this incidence by years and by months. Everything appears to support the theory that the Anopheles can only become dangerous when the temperature reaches a certain height. The plasmodium appears to be viable only in certain particular years and in the months of July and August. The mosquitos then become infected but soon go into hibernation, the sporozoa persisting only in the salivary glands of the insect. The infection then appears in man in the following May, for during the cold weather the parasites complete their development and are for the first time a menace to man.

The Eye Symptoms of Recurrent Fever.—Kuhlefelt goes exhaustively into this subject which is of interest because this affection is a spirillosis, and hence might show some parallelism with syphilis. The eye symptoms of this affection have attracted attention in Finland since 1866. The most common of the symptoms is cyclitis, which is doubtless often overlooked. This lesion, despite its protracted course, is not to be regarded as chronic cyclitis, but the persistence of the symptoms is simply the result of delayed absorption. The lesion therefore is acute cyclitis. Iritis when present is as a rule simply a complication of cyclitis, or in other words iridocyclitis; primary iritis is rare, but does occur. In iritis of any type the formation of synechiæ may occur. Typical iridocyclitis is said to be rare and until recently had been seen only by Uhthoff. Conjunctival and subconjunctival hemorrhages may occur. Other eye affections in recurrent fever are probably best regarded as chance coincidences. The existence of a specific choroiditis is to be doubted. Serous choroiditis could not account for the alleged symptoms, while the ophthalmoscopic finds of exudative choroiditis have never been reported.

Nederlandsch Tijdschrift voor Geneeskunde.

June 8, 1918.

Acute Myeloblastic Leukemia.—Hannema reports a case of this affection in a man aged 39 years who before his present illness had been quite healthy. In July, 1917, he had a tooth pulled and the bleeding which accompanied the act persisted for 4 or 5 hours. This hemorrhage stood in some association with a preceding stomatitis with suppurative gingivitis. The gums continued to bleed off and on and he began to show pallor. The appetite remained good and there was no emaciation. There was no other hemophilic tendency. He entered the hospital in October, a very pale subject with pale mucosae. There was a marked *fetor ex ore* and the gums were everywhere much swollen and covered with a foul grey deposit. The gums bled readily and pus could be expressed from them. The physical examination was largely negative, as far as organic lesions were concerned. The blood examination showed hemoglobin 50 and erythrocytes 2,130,000. Leucocytes were 10,000. The further finds were atypical and the case is summed up provisionally as one of infectious stomatitis with a peculiar reaction of the bloodmaking organs. The blood picture was quite devoid of any evidences of regeneration. It was that of aplastic anemia without signs of hemolysis. There was chiefly an insufficiency of the bone marrow. The author mentions for the first time enlarged spleen. The patient failed rapidly, the hemoglobin falling to 10 and the erythrocytes to 900,000. Death occurred Oct. 24, about three weeks after admission. Autopsy revealed only intense anemia. Only after a microscopical examination of the spleen, liver and bronchial lymphnodes was the diagnosis of acute myeloblastic leukemia made.

Psychogenic Urticaria.—Van de Roemer refers to a case recently reported in the Tijdschrift of emotional urticaria and is able to duplicate it with an observation of his own. The patient was a medical student and the case occurred in 1915. The entire body broke out at once but the lesions were more pronounced on the exposed surfaces. The lesions began as small papules with a red areola. The greatest distance was 3 mm. between the spots. He never had experienced an emotional outbreak of hives until he was 21 years old. They appeared under all kinds of conditions, in summer and in the coldest weather, during active labor and when quietly seated. The only *sine qua non* was some emotional experience. Psychogenic sweating was always associated with the hives.

Book Reviews.

THE MEDICAL CLINICS OF NORTH AMERICA. Vol I, No. 5. Chicago Number. March, 1918. Price, $10 per year. Published by W. B. Saunders Company, Philadelphia and London.

SOME excellent cardiovascular material is presented by Dr. C. L. Mix and A. R. Elliott in discussions of the aortic disease, aneurysm, syphilis of the aorta, and the fundamental principles underlying the diagnosis of the more common cardiac lesions. Dr. S. Strouse demonstrates two cases of diabetes in twins, a boy and a girl. The glycosuria appeared about the same time in both. He also takes up the Karell treatment of edema and makes some observations on the importance of details in the treatment of angina pectoris. Dr. Charles A. Elliott shows three cases of leukemia; one, of the myelogenous type, was treated with radium and followed by splenectomy. Under the influence of radium the spleen was reduced in size, so that it weighed only 300 grams when removed. The leucocytes were 311,200 at the beginning of treatment and decreased to 11,700 when the patient left the hospital in good condition. Another case of myelogenous leukemia and one of lymphatic leukemia were treated with radium radiation and materially benefited. Elliott believes that this form of therapy is much more effective than any other. Not only do the leucocytes return to within fairly normal limits, but the red blood cells and hemoglobin increase decidedly. Next in order is a clinic by Dr. F. Tice, on epidemic respiratory infection, in which he takes up the particular variety of infection that was prevalent in Chicago last winter. Dr. C. S. Williams presents a case of Vaquez's disease. Dr. M. Portis gives a very interesting clinic on the differential diagnosis of lesions of the right upper quadrant. Following is a list of the remaining clinics in this number: Reflex gastric disturbance and epigastric pain, by Dr. J. C. Friedman; tuberculin skin reactions in diagnosis of tuberculosis in childhood, by Dr. J. H. Hess; nephritis, by Dr. F. Wright; splenomegaly and cirrhosis of the liver, by Dr. A. F. Byfield; insomnia and hysteria, by Dr. R. C. Hamill; asthma in Children, by Dr. I. Abt; Roentgen examination of the appendix, Dr. M. J. Hubeny; pyelitis in the newborn, Dr. H. F. Helmholz.

THE COST OF CLEAN CLOTHES IN TERMS OF HEALTH. By LOUIS I. HARRIS, Dr.P.H., M.D., Director, Bureau of Preventable Diseases, Department of Public Health, New York City, and NELLE SCHWARTZ, Executive Secretary, The Consumers' League of the City of New York.

THIS little brochure appears without reference to its publication and bears no date. The subtitle is "A Study of Laundries and Laundry Workers in New York City." There are staffs of subeditors from the Board of Health and Consumers' League. The subject matter comprises a complete account of the laundry industry of the metropolis, apparently the first effort of its kind, for the territory covered. The only works cited are similar reports of the industry in the State of California and City of Milwaukee. The book is well illustrated by photographs and other graphics, tables, examination blanks, etc., and should be read by all who are interested in civics, occupations, hygiene, and cognate subjects.

DIFFERENTIAL DIAGNOSIS. Volume II. Presented through an Analysis of 317 Cases. By RICHARD C. CABOT, M.D., Assistant Professor of Clinical Medicine, Harvard University Medical School, Boston; Chief of the West Medical Service at the Massachusetts General Hospital. Second Edition, Revised. Profusely illustrated. Price, $6.00. Philadelphia and London: W. B. Saunders Company, 1918.

THIS volume is on the same general plan as the first part which appeared a few years ago. In place of the usual text-book method of treating this subject, the author takes some prominent symptom and presents in detail some cases in which this symptom was a marked feature. These cases are analyzed and discussed; and the reader gets the advantage of being present at a clinic, where all of the possibilities are brought forward and one by one are eliminated, until a diagnosis is reached. The volume is most interesting as well as instructive; and the practitioner will derive real benefit from studying some of the cases here presented. If the reader does not always agree with the author's conclusions he will, at any rate, have had the benefit of thinking over the case; and Dr. Cabot's views are always stimulating. The Symptoms considered in this volume are: Abdominal and other tumors, vertigo, diarrhea, dyspepsia, hematemesis, glands, blood in the stools, swelling of the face, hemoptysis, edema of the legs, frequent micturition and polyuria, fainting, hoarseness, pallor, swelling of the arm, delirium, palpitation and arrhythmia, tremor, and ascites and abdominal enlargement. The book contains 317 cases, with discussion, and will afford profitable reading for one year, at the rate of a case a day.

INTERNATIONAL CLINICS. Edited by H. R. M. LANDIS, M.D. Vol. I. Twenty-eight Series, 1918. Price, $10 per year. Philadelphia and London: J. B. Lippincott Company.

THE present volume of "International Clinics" contains a list of seventeen contributors, fourteen of whom are American. The subject-matter of his volume follows the customary arrangement into clinics and lectures on the various branches of medicine. Among the foreign papers that of Dr. Charles Greene Cumston on "Injuries to the Cranium and Brain in Warfare" is particularly worthy of note. Dr. W. S. Lee of Philadelphia reports the successful treatment of an enormous carbuncle on the back, 7½ inches in diameter, by means of deep crucial incisions and dichloramine-T antisepsis. The lesion healed in seven weeks. Lee calls attention to the value of secondary suture of infected wounds after their chemical sterilization with Dakin's solution. Dr. F. P. Weber of London has an interesting and instructive article on "Some Pathological Conditions of the Nails," in which he discourses on various forms of leuconychia, transverse grooving, incurved nails with clubbed fingers, and congenital ingrowing nails. The other articles are sufficiently diversified to make a well-balanced number. The illustrations are numerous and help to visualize the context. Finally, there is the annual general review of medicine, which gives the reader a synopsis of the principle advances made in all branches during 1917.

THE PREVENTION OF VENEREAL DISEASES. By OTTO MAY, M.A., M.D. (Cantab.), M.R.C.P. (London), Late Hon. Secretary, National Council for Combating Venereal Diseases. Price, $3.00. Oxford University Press, American Branch, 1918.

AS a consequence of the social conditions incidental to and arising out of the present war, venereal diseases are increasing and their ravages have prompted the author to present his views on their prevention. He realizes that their ultimate extinction by the abolition of promiscuous sex-relations is Utopian. In agreement with all other writers on the subject he emphasizes the importance of childhood education in self-control and morality. He views with more or less scepticism the practicability of governmental control of infected individuals and points out the flaws in these statutory enactments. Chapter III, entitled "Prostitution and Venereal Diseases," shows the fallacies of segregation and registration and is in accord with the writings of all modern practical sanitarians. Greatest stress is laid on prophylaxis or personal prevention, which, after all, is the most material and practical preventive measure. Little or no technique of this procedure is described and that little is open to a serious question as to its value. The closing chapter on venereal disease and marriage is excellent, and with regard to syphilis is based on Fournier's work and the opinion of J. E. Lang, F.R.C.S., who prefers to trust the clinicians' judgment rather than laboratory findings. With regard to gonorrhea, Kidd's test is accepted, which consists of bacteriological tests of the expressed prostatic and vesicular contents. Of the four appendices, the first only is of consequence. It consists of a lecture to troops on the nature and seriousness of venereal diseases in words intelligible to the laity. The work is dignified, serious, and timely.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held May 27, 1918.

THE PRESIDENT, DR. HOWARD C. TAYLOR, IN THE CHAIR.

Some of the Fundamental Scientific Principles of Radium Therapy.—Dr. WILLIAM DUANE presented this communication. He said that by fundamental principles he meant those general laws dealing with the radioactive substances, such a large mass of which had been collected during the past twenty-one years since Professor and Madame Curie discovered radium. Dr. Dunne showed pictures of Professor and Madame Curie and related his personal experiences in their laboratory. At the time Madame Curie discovered radium she was a student at the University of Paris, and the work she did in discovering radium represented her thesis for the degree of doctor of science. It was perhaps the most important doctor's thesis that had ever been presented to the University of Paris or to any other university, for that matter. Pictures were also shown of the place from which we obtained the ores containing radium and other radioactive substances. The first ores the Curies used came from Bohemia; those we were using in New York and Boston came from Colorado, and the radium was extracted in this country. Radium-bearing ores were distributed throughout the surface of the globe. Since the discovery of radium some thirty other substances, also radioactive, had been discovered, each one of which was a chemical element. Each one of them, however, was constantly transforming itself into another element. In addition to transforming themselves from one element into another they were all peculiar in that they were radioactive. The speaker then described the way in which they obtained the radium emanations that were being used in Boston and New York, and called attention to two new methods of using radioactive substances in America. The first was called the prolonged radiation method, because by means of it one could radiate tissues for two or three weeks or a couple of months. In order to do this a capillary glass tube, very small, containing a few units of emanation, was placed in the tissue by means of a trocar and left there. One-half unit of emanation would disappear in four days; one-half of the balance disappeared in 3.85 days; in sixteen days there was one-sixteenth left. By this second method three radioactive substances, A, B, and C, were deposited on anything that came in contact with the gas emanation. C was most active. Bringing it in contact, in a glass tube, with a piece of metal, one could make that metal intensely radioactive. This represented an intense radiation for a short time. In the application of radioactivity they had a set of rules that were very flexible. The radiation varied widely; the application might be either an intense radiation lasting a short time or a very weak radiation acting over a long time.

The Influence of Radium on Cancer Tissue.—Dr. JAMES EWING spoke on this subject from the standpoint of one interested in the general progress of cancer research. He stated that, since 1904, it had been his lot to make periodic visits of investigation at institutions abroad and in this country, and he had made one or two observations of interest in regard to therapy in the treatment of cancer. The first was that these institutions were always in the habit of using some constitutional agent in the treatment of inoperable cancer, and what was used in one institution was not the same thing as advocated in another. The list of agents used was very large. The second observation made was that many had definite results from these agents; they all claimed and professed to be able to prove certain results. In making a comparison of the effects of radium one fact stood out, and that was that while the results of these various agents were no doubt visible to the observer, they were so uncertain and unusual that Tuffier described them as paradoxical, and there was always the question whether the results were not due to some spontaneous change in the course of the disease. With radium the results were different in that if the same amount of radium were applied, through the same sort of filter, to the same type of cancer, the result was invariably the same. The advent of an agent that could do something to cancer that was not open to argument was most welcome. Radium was to be relied upon to do the same thing every time under the same circumstances, the difficulty being to provide the same circumstances. Radium was a specific in the sense that it was a substance that produced results that the speaker had not seen duplicated in any other way and produced changes which one would not see under any other circumstances. The entire series of changes followed by regression was not produced by any other agent with which the speaker was familiar. The changes which took place were controlled by one or two general principles. Radium exerted its chief effect upon the nucleus of the cell causing a peculiar liquefaction, necrosis, and atrophy. Another principle of its action was its effect on the underlying tissue in which the tumor cells were growing. It acted on the soil in which the tumor cells were growing, bringing about a natural healing process. It stimulated the growth of granulation tissue which excavated the cells and caused an exudation of various round cells; this he interpreted as a process of healing because the scar was very even and the end result a natural process. The healing effect of radium on the underlying tissues was due to stimulation of normal regenerative processes on the part of the normal tissue. This being so, one might assume that no matter what the type of cell it would respond to the action of radium. There was a great difference in the way in which different types of cells responded to radium. Some tumors were very resistant, some very susceptible. The chemical and morphological structures of tumors were very different and one must expect a very different response to radium in the various types of tumors. This fact should force us to pay more attention to the physical and chemical constitution which determined their response to radium. Dr. Ewing said he would not prophesy what radium was going to do in the future. In one respect it was far from being an ideal cancer cure. When applied locally it was efficacious but it had no constitutional influence at all. It might be possible by injecting it in salt solution to accomplish this, but that was a matter for future study. The local application of radium produced its effect over a territory more or less limited and the results so far attained were best in those conditions. As a remedial agent in advanced and inoperable cases, Dr. Ewing did not believe its results would ever represent its greatest usefulness. It acted in a local center only. If one gave large doses bad toxic effects followed. All the changes he had seen in many autopsies had indicated its limitation in the average case. The proper cases for radium treatment were the early forms of the disease.

Lantern Slide Demonstration of Uterine Cancer Treated with Radium.—Dr. HAROLD C. BAILEY made this presentation. He said that what Dr. Ewing had just said fell right in line with what he wished to demonstrate by the slides he was about to show. The future aim of the institutes that had large masses of radium would be, insofar as uterine cancer was concerned, to treat early cases in which the disease was not far advanced in the parametrium. Dr. Bailey showed illustrations of six cases in which hysterectomy was done after radiation. These cases were treated by the old method of small doses with replacement of the capsule in the same spot. Another series of cases treated with the idea of cross raying were shown. Dr. Bailey explained the attempts at regeneration shown in the specimens that had been subjected to radiation.

Treatment by Radium of Cancerous Mucous Membranes.—Dr. HENRY HARRINGTON JANEWAY presented this communication in which he called attention to the importance of knowing accurately the indications for the use of radium. At the present time there was a wide difference of opinion as to the place in cancer therapy which radium should occupy. This difference of opinion was perhaps most strikingly expressed in the question "Should some of the more important forms of cancer be treated by radium in their early stages, in an attempt to cure the disease by this agent, instead of by operative removal; or should radium be used alone as a palliative or supplementary means to

the usual methods of dealing with the disease?" At the Memorial Hospital, they had been encouraged to treat a rather large number of operable cancers of the mucous membranes. The remarkable improvement in some of the cases treated palliatively had not alone stimulated this attempt, but more especially the favorable result obtained in many early cancers in patients refusing operation, or in whom operation was contraindicated for other reasons. Two facts had been demonstrated by this experience: First, that within the time limit within which they had been working, single applications were often sufficient to cause apparent complete retrogressions, and, second, that in the larger lesions, in which this favorable result was not obtained, the lesion had become much more of an operable one than it was before treatment. There had been obtained, for instance, complete retrogressions within the time limits within which they had been working, in 21 cases of cancer of the lip, eight cases of cancer of the superior maxilla, including two which originated within the antral cavity; nine cases of cancer of the tongue and in one instance a large growth was greatly reduced in size and had since been removed under local anesthesia, without recurrence up to date, an interval of five months; in three cases of cancer of the tongue, and probably in two others not traced to date; in one patient with cancer of the soft palate. A number of patients with cancer of the larynx had been greatly improved, but none had been cured by radium alone, although in several there was a complete disappearance of the disease for a time. In one patient with advanced cancer of the larynx, an incomplete but marked regression of the disease was caused by the radium. At this stage the speaker removed the larynx and the patient had now been free from recurrence for one year, and was able to speak loud enough to be heard across a small room. In cancer of the larynx definite temporary improvements had been obtained from single treatments. Cancer of the rectum offered a most important and fruitful field for radium therapy. The operative treatment of cancer of the rectum had been disappointing. Moreover the necessity of establishing an artificial anus in the majority of the cases was a most serious drawback to the operative treatment of cancer of the rectum. While he could not, at the present time, claim with the same certainty favorable results in the treatment of cancer of the rectum that he could in the more accessible cancers of the mucous membranes of the mouth, yet the results thus far obtained, fully warranted the management of early cancer of the rectum by radium. If the entire management of cancer of the rectum should not be by radium, at least the preliminary treatment should be by radium. Among the patients whom they had treated clinically, complete retrogressions had been obtained in eight patients. Of these patients, one was treated in August, 1914, and when last heard from, a few months ago, he was well and working. Three other cases were at least clinically free from the disease at an interval of one year from the time of their treatment. Life was prolonged in the case of two others in comparative comfort for two years. The majority of their patients had very advanced lesions and the end results in these cases must be wholly discounted. The technique of the treatment of cancer of the rectum was constantly improving. Unquestionably the most promising field of radium therapy among the mucous membrane cancers was cancer of the uterus. It was possible to safely give these cancers very large doses, and it was doubtless due to this fact that, in the writer's experience, practically uniformly good results had been obtained. Among his own patients he had two who had primary growths of the cervix, involving most of the vaginal surface of the cervix from which positive microscopical sections were obtained, who had remained well after one treatment for a period of two years up to the present time. At least five other patients promised equally good results to date. The mixed tumors of the parotid, many of them being fairly cellular with the carcinomatous elements pronounced, had given almost specific response to radium treatment. They had had five striking results among these tumors. They had wholly omitted reference to the epithelioma of the skin, not because the benefit conferred upon these patients was a life saving one, but because the problem was relatively simple. The real problem in the treatment of cancer today was the successful management of cancer of the mucous membranes. It was a problem unsatisfactorily solved by surgery alone. In cases of cancer, in equal stages of growth, the character of the end results among cases cured by radium, coupled with the ease to the patient by which this result could be obtained, far surpassed the results of surgical ablation. The possibilities of the radium treatment of cancer were by no means exhausted. When they began their work at the Memorial Hospital, they little dreamed of the step by step improvement in technique which they had already accomplished. This improvement promised satisfactory and fairly uniform results for the future.

Dr. JOSEPH BISSELL said that to listen to the conflicting statements of various physicians it would seem that there was only one thing easier to prove than the fact that cancer was favorably affected by the proper use of radium and that was to prove that improperly used radium did a great deal of harm. The results of radium treatment seemed to depend on the point of view, the amount of radium used, the form of cancer, and the amount of enthusiasm of the observer. He did not agree with Dr. Ewing that radium should not be used in inoperable cases and that because of the view that Dr. Ewing had expressed, namely, that radium made cancer regressive. Why not take these cases and divide them and treat each piece as a local cancer? Dr. Bissell stated that his experience with radium in cancer of the mucous membrane had always been satisfactory, but he never saw cancer of the tongue without feeling that the patient was doomed. Cancer of the rectum he had seen absolutely disappear. Radium had great possibilities ahead of it. It caused the disappearance of lymphosarcoma which could not be removed with the knife. Many cases of Hodgkin's disease improved under the proper application of radium. He had seen a number of cases of fibroid of the uterus, including pedunculated fibroid, that had disappeared as surely as though removed by the knife and one did not destroy the function of the organ by the radium treatment, so there was left another child-bearing unit that might be needed if this war went on. If one could not remove cancer without mutilation he did not see why radium should not be preferred to excision as in many cases, rodent ulcer, for instance, it caused the disappearance of the growth. Recurrent nodules in the breast were repeatedly caused to disappear. In the inoperable cases of cancer one had no choice. They might not be cured, but the patient could be relieved of the odor and in most cases bleeding could be prevented. Under radium treatment the patient would be mentally better and would be restored to the comfort of living and the possibility of hope; radium was worth while for this reason alone.

Dr. BENJAMIN BARRINGER said that rather than attempt to discuss the very comprehensive papers presented here this evening he would like to give a very brief review of their work at the Memorial Hospital in the radium treatment of carcinoma of the bladder. As to the curability of carcinoma of the bladder, there was no reason why carcinoma should not be more often cured. It was long confined to the bladder. An instance of this was a patient autopsied at Bellevue Hospital who had a carcinoma completely filling his bladder. There was perhaps room left in his bladder for one or two drams of urine. There were no metastases in any other part of the body. This case was not an exception, but rather the rule to the papillary variety of carcinoma of the bladder. Again, often the diagnosis could be made early because of the one early and fairly constant symptom—hematuria. Nearly all bladder tumors bled early in their existence. There was no other internal organ which might be so completely examined as the bladder. It could be palpated suprapubically, the base could be palpated rectally, the interior could be examined by means of the cystoscope and pieces excised for microscopical examination. Notwithstanding all this, they had signally failed to cure bladder tumors. The reason for

this was principally the fact that most bladder tumors invaded the base of the bladder and later either ureter. The base was difficult of surgical access, and excising and reimplanting one or another ureter was considerable of a surgical operation. The application of radium in bladder tumors was made through the urethra through the sheaf of the cystoscope. As to untoward results of radium they had had no deaths from the radium application. They had had a number of burns, and when such burns occurred they were long in healing, caused a good deal of pain and frequency of urination. They had to be controlled largely by morphine. Better technique and more accurate application of the radium to the bladder tumors ought to prevent radium burn. They had had 43 cases of carcinoma or indurative carcinoma, or a combination malignant papilloma, the rest had been either papillary carcimona or indurative carcinoma, or a combination of the two. But two of the cases could be classified as early operative cases, and these two had been too recently treated to report finally upon them. Of the other 41 cases, some of them might have been operated upon; if so the operation would have been a partial or a total cystectomy. On the whole, operation would have offered but slight chance of cure. As to the benefit done, in operable cases, he believed the one thing that radium did was to check the hemorrhage. In most cases it did this and he believed this meant that the radium had attacked the carcinoma, and the very fact that the hematuria was checked encouraged the patient a great deal if it did nothing more. These 41 cases had been cured, as far as the bladder was concerned, one for 23 months, one for 12 months, one for 7 months, and one on one examination. All of these cases were advanced cases, one a post-operative case, three were confirmed microscopically as "carcinoma of the bladder." In two cases the tumor had recurred after being removed by radium from the bladder. Three or four more cases of the 43 would probably later go into the cured column as far as the bladder was concerned. It was on this record of five cases cured, as far as the bladder was concerned for various periods of time, that he based his claim for the efficiency of radium treatment in carcinoma of the bladder. One of these patients came to him about two and one-half years ago with a diagnosis of "inoperable carcinoma of the bladder." She had a sloughy extensive carcinoma (proved microscopically by Dr. Ewing), occupying the left side of the bladder and obscuring the left ureter. She was given one dose of radium and experienced for 48 hours frequent (every hour) burning urination. Sixteen days later she was cystoscoped and the speaker with Dr. Keyes, whom he wished to see the case, were present. Much to his astonishment, he found the tumor was gone. The radium had evidently been exactly in the right place and exactly the right amount. That case had stayed cured for twenty-three months. The speaker had never known another case in which the carcinoma was so rapidly removed as this.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 26, 1918.

DR. WILBUR WARD IN THE CHAIR.

Three Cases of Hydatid Mole.—Dr. M. A. SHLENKER reported these cases. He stated that his reason for bringing them before the section was because there seemed to be quite a variance of opinion as regards the frequency of their occurrence. In the older textbooks and in the majority of recent ones the statistics of Madame Biovin were quoted, stating that hydatid mole occurred only once in 20,000 cases. The textbooks by Williams on this subject quoted Williamson's statistics stating that they occurred as often as once in 2,400 cases. In the writer's conversation with many obstetricians and general practitioners he had been impressed by the fact that they did not regard this condition as unusual but thought that it was of rather frequent occurrence. He, too, was of the opinion that these cases occurred much more frequently than they were reported, though not with such frequency as one might be led to believe. The important point in the consideration of this subject was the fact that these cases often found a fertile focus for the implantation and proliferation of one of the most malignant and dreaded conditions, chorioepithelioma. This condition was found to be secondary to molar pregnancy in about 16 per cent. of the 210 cases collected and reported by Palmer Findlay. He regarded these figures as rather high, taking into consideration the fact that these cases did not seem to be reported as frequently as they occurred. The cases and specimens presented occurred at the Gouverneur Hospital within a comparatively short period of time, about 15 months. The writer had investigated the hospital records as far back as 1911 and found that four cases were recorded. Two of the latter cases died, one after a curettage, the patient being septic at the time of her admission to the hospital; the second case, which presented a protruding mass, was subjected to laparatomy and died shortly afterwards. The remaining patients, except for one who was lost sight of, had kept well and reported this week in perfect health. During this period the hospital had cared for 3,071 obstetrical cases.

CASE I.—This patient, 42 years of age, was admitted to the Hospital on December 15, 1916. She gave a history of having had four full term pregnancies and two miscarriages, and at the time of her admission was apparently gravid six months. She began to flow the day before for the first time. During the night the bleeding became profuse. The uterus was enlarged to the height of the umbilicus and the cervix was dilated sufficiently to admit one finger. The abdomen was not distended. A palpable mass extended up to the umbilicus, corresponding to a pregnancy with a six months amenorrhea. On December 24 the patient expelled a multicystic mass. Dr. John F. Erdman then performed a vaginal hysterectomy. This patient was now well.

CASE II.—Dr. Shlenker said this patient, 19 years of age, was admitted to the hospital on February 20, 1918. She gave a history of having suffered during her entire menstrual period for the past two years. Her health was apparently excellent until February 14, 1918, when she began to spot. At the end of four days the bleeding became profuse and the patient sought the hospital. At this time abdominal palpation revealed the uterus three fingers' breadth above the symphysis. The cervix was soft and admitted one finger into the os. The fundus was enlarged to the size of a three months pregnancy and reached about three fingers' breadth above the symphysis. On February 20 the patient expelled a bloody grape-like mass. A disagreeable discharge continued; hence the uterus was curetted and explored digitally. The scrapings were submitted to the pathologist who made a diagnosis of hydatid mole without any evidence of malignancy. The Wassermann reaction was negative in this case. Vaginal examination, on March 5, showed the uterus slightly enlarged and in normal position. The ovaries were enlarged and felt as though they were cystic. This patient was discharged cured with instructions to report to the outpatient department within a month

CASE III.—This patient, 45 years of age, was admitted to the hospital on December 10, 1917. She had been married at the age of 22 and had had eight full term pregnancies and four miscarriages. About two weeks previous to her admission to the hospital she began spotting and four days later the bleeding became constant and more pronounced. The patient complained of great abdominal pain and frequent desire to urinate. At the time of her admission she appeared septic. The abdomen was greatly distended, the fundus of the uterus reaching to the umbilicus. The uterus was enlarged, corresponding to a six months pregnancy. No fetal heart sounds could be heard nor could any fetal parts be felt. Owing to the weakened condition of the patient she was kept under observation and treated conservatively. On January 8, 1918, she expelled a large polycystic mass which the pathologist reported to be a hydatid mole with no signs of malignancy. The patient left the hospital against advice. On March 21, 1918, the patient was advised to return to the hospital. After being home four weeks she began to spot and immediately went to Bellevue Hospital,

where she was admitted. Her vagina was packed and she was given internal medication. At the end of three days she returned to her home. Shortly afterward she began to flow. This lasted eight days and was interpreted as her normal menstrual flow. On her return to the hospital, vaginal examination showed the uterus slightly enlarged in its transverse diameter, corresponding to a six weeks pregnancy. It was in good condition and freely movable. The patient had been asked to return within the next month for a curettage.

Dr. HERMANN J. BOLDT said that a certain percentage of hydatid moles were likely to become malignant and the question was in what percentage of these cases chorioepithelioma was likely to develop. He believed that it was most generally considered that the original condition was a hydatid mole in most cases of chorioepithelioma.

Dr. SHLENKER stated that in about 50 per cent. of all cases of chorioepithelioma, the hydatid mole was the important etiological consideration. In the treatment of these cases there seemed to be a tendency to resort to operations such as a panhysterectomy, which precedure, in his estimation, was rather radical. Recurrences of a malignant nature occurred in only 10 or 15 per cent. of these cases. These cases should be treated by a simple but complete evacuation of the uterine cavity, with a digital exploration of the same. Dr. Ries of Chicago recently reported the presence of chorionic villi in the uterus, presumably of eighteen years duration. The point to be emphasized was that these moles did occur much more frequently than they were reported, and caution should be sounded against too radical procedure for their relief.

Uterine Tumors.—Dr. HERMANN J. BOLDT presented four *carcinomatous uteri* removed during the past year. The *first* was removed from a woman 35 years of age, with typical cancer of the vaginal part of the cervix. The upper part of the vagina was slightly involved, consequently a considerable part of the vagina was also extirpated. A smooth recovery followed. The *second* patient, 58 years of age, had been losing a little blood at irregular intervals during the past few months. The condition was obviously a carcinoma of the cervix. Because of the obesity of the patient and her somewhat advanced age, a vaginal extirpation was decided upon. Recovery in this case was uninterrupted. The *third* specimen was an adenocarcinoma of the body of the uterus, removed from a patient 63 years of age, who had had a typical bleeding for about four months. The abdominal operation was done because of the size of the uterus and the consequent risk of soiling the field of operation had it been done per vaginam. From an experience covering many years, the vaginal extirpation was preferable only in patients in whom the uterus was freely movable, not so large that it could not be readily brought down nearly to the vulval opening, and then the technique should be modern, that was the isolation of the ureters as advocated by Schauta. The *fourth* specimen was removed from a woman, 49 years of age, who had been having irregular bleeding for four months, for which she had received local treatment. The pathologist's report showed adenocarcinoma. The operation was done by the abdominal route. An uneventful recovery followed.

The next specimen was one of *myoma of the uterus* with complete obliteration of the uterine cavity. He stated that the patient was 45 years of age and complained only of intense pelvic pain; there was no bleeding. The adhesions of the tumor to the surrounding structures were diffuse and firm. The pelvis was tightly filled by the tumor, and yet the patient did not complain of constipation. Technically the operation was difficult. Dr. Boldt said he recalled but one instance in which there was an obliteration of the uterine cavity in the case of fibromyoma, and an absence of bleeding as a result. The symptoms in that case, too, were those caused by pressure from the tumor. Recovery was uneventful.

Dr. Boldt next presented a specimen of *myofibroma uteri* removed by morcellement. The vaginal operation was especially to be selected when the tumors were not above the brim of the pelvis, and when the patients were very obese. In both instances profuse bleeding was the indication for operation. Of course it was true that when one was not accustomed to doing such work per vaginam, it might be found rather unsatisfactory; but each method had its indication.

A *submucous myoma* was the next specimen presented. The uterus had been treated both with radium and the *x*-rays, but no lessening of uterine bleeding was accompiished. This was evidence that no one method of treatment was adequate.

The last specimen was one of *intraligamentous myoma*. The patient suffered principally from pressure symptoms; the bleeding at the menstrual period, while quite profuse, was not so copious as one would expect from the appearance of the growth.

Dr. Boldt, after presenting these specimens, said that in operations for carcinoma of the corpus uteri, when the uterus was small, he preferred the vaginal route for he felt that in operating by this route there was less danger of trauma and of spreading the carcinoma. He also preferred the vaginal route for patients who were somewhat advanced in years. In all obese women he took the vaginal rather than the abdominal route. An expression of opinion in reference to the election of the vaginal and abdominal routes in carcinoma as well as in myoma would be greatly appreciated.

Dr. HERMANN GRAD expressed the opinion that in many of these obese patients the vaginal route was preferable and particularly in those women who were somewhat advanced in age, and in cases of carcinoma in which it was impossible to do a radical operation. The results were practically as good by the vaginal route as by the abdominal route and the mortality was less in the vaginal operation. This subject was discussed in former years before Wertheim brought out his operation, and some men felt that the vaginal route was not as satisfactory as the abdominal. He believed we should take into consideration the technical needs, and if this were done we should find that in stout women of advanced age the results were as good and the mortality less with the vaginal than with the abdominal route.

Hydatidiform Mole.—Dr. GEORGE L. BRODHEAD presented this specimen which he said he had brought as a part of the discussion on Dr. Shlenker's paper. In their last 4,000 cases at the Harlem Hospital they had had three moles. The patient from whom this specimen of vesiculæ was taken was a primipara, 26 years of age, who menstruated in August, September, and October, 1917, each time one day. In December she bled for several days. On January 5 she had a hemorrahge. From February 1 to March 19, she bled some each day, and, on March 19, was admitted to the Harlem hospital. The uterus at this time was the size of a six months pregnancy. No fetal heart sounds were heard. At the time of her admission the patient's pulse was 80 and her temperature 98.6°. After being in labor three and three-quarter hours she discharged a hydatid mole, which weighed about two pounds with no trace of the fetus. Her temperature on the day of labor went up to 103.6° Fahr. and for the last three days had been between 99° and 100° Fahr. She had complained of some pain in her back for several days, but to-day was getting along very nicely. If there was any further bleeding they would have the patient curetted and the scrapings examined.

Dr. WARD asked if any one had had a specimen of hydatid mole in which he had been able to find any trace of fetus.

Dr. SHLENKER said he had no specimen in which he had been able to discover any trace of fetus, but instances had been reported in the literature of the occurrence of hydatidiform cysts associated with twin pregnancy, one child surviving.

An Improved Murphy Drip.—Dr. H. DAWSON FURNISS presented this apparatus. He stated that in using the ordinary Murphy drip the great difficulty had been to so set it up that there should not be excessive pressure. He had seen it used in many hospitals and the overflow tube had been generally so placed that when the tube to the rectum became filled or the patient strained to pass gas there was a pressure of three to three and one-half feet. To overcome these difficulties he had constructed a simple apparatus. The first one made was all glass and much neater than this one but was difficult to clean. This apparatus consisted of a strong glass tube 1½ inches in diameter and closed

at each end with rubber stoppers. The lower rubber had two perforations, one in the center and the other eccentric. Through the central one was passed the tube of a funnel, the top of the funnel being 2 inches above the stopper. Through the eccentric opening was passed a tube, the top of which was flush with the stopper. The upper stopper was bored the same as the lower. Through the center opening passed a tube, the lower end of which was drawn so that it was 1/32 of an inch in diameter; this was the feed tube. The eccentric opening was for a small tube, the purpose of which was to prevent siphonage when the overflow was working. In order to use the apparatus it was clamped to a suitable standard or to a portion of the bed so that the top of the funnel was only eight or ten inches above the rectum. A rubber tube led from the funnel to the rectum. From the eccentric tube a rubber tube passed to a basin or pail on the floor. To the tube on the center of the upper stopper was connected the supply of fluid, and the rapidity of the feed was controlled by a suitable pressure clamp. The fluid dropped into the funnel and went to the rectum. Should the flow be too fast or the patient strain the fluid rose in the funnel overflow and passed out by the tube to the pail on the floor. A small air vent in the upper stopper prevented siphonage after filling of the overflow. Dr. Furniss said he had used this apparatus with great satisfaction. In one case the drip was given for seventy-two hours and was discontinued only when there was no further necessity for its use.

Dr. HERMANN GRAD asked whether the fluid could be kept warm with this apparatus.

Dr. FURNISS replied that he had made no provision for heating the water.

Dr. GRAD said he had practically given up the use of the Murphy drip in cases in which the rectum was intact because he found that if one put 2 ounces of fluid into the rectum every two hours it was much easier for the nurse than using the Murphy drip and it accomplished the same object; the patient got essentially the same amount of fluid as with the Murphy drip. If he found that the patient needed more fluid than could be given in this way he gave the fluid by hyperdermoclysis. It seemed to him that Dr. Furniss' apparatus provided very nicely for all details in the use of the Murphy drip.

Hematogenous Infection of the Ovary.—Dr. SOLOMON WIENER presented this paper in which he stated that hematogenous infection of the ovary might occur just as any organ or tissue of the body could become the nidus of growth for pathogenic bacteria carried in the circulating blood. The frequency and importance of such infection of the ovaries had not received due attention or emphasis. Dr. Weiner referred to the work of Rosenow and Davis (*Journal of the A. M. A.*, April 15, 1916) and said that in summarizing these writers laid special stress upon the finding of the streptococcus in the fibrocystic ovaries of a young woman with complete atresia of the vagina. In order to rigidly exclude infection by extension from the genital tract the following conditions must prevail: (1) Intact hymen; (2) no coitus; (3) no history or evidence of gonorrhea or vulvovaginitis in infancy or childhood; (4) no vaginal discharge whatsoever; (5) no local or intrauterine medication or instrumentation; (6) no focus of suppurative inflammation within the peritoneal cavity. When all these conditions had been excluded there still remained cases of undoubted hematogenous infection of the ovary. These usually occurred in pre-existing cystic conditions, especially in the remains of the corpus luteum. Thus far the best known and most frequently reported form of such infection was with the *Bacillus typhosus*. Such a case the writer had previously reported (A Study of the Complications of Ovarian Tumors, *American Journal of Obstetrics*, Vol. 72, No. 2). Dr. Wiener said he wished now to report a case of hematogenous infection of the ovary with the *Streptococcus hemolyticus*. which occurred in a high-school girl, 18 years of age. The patient gave a history of right-sided abdominal pain two months before admission to the hospital and since that time she had been troubled with constipation and cramps; these had become much worse during the past three weeks. Examination showed the adomen lax and tympanitic. In the right lower quadrant there was a large firm mass dipping into the pelvis. The hymen was intact; there was no redness of the urethra, the Bartholin ducts, or vulva, and no vaginal discharge whatsoever. Examination with a small endoscope showed no discharge from the cervix. To the right side of the uterus was a firm, slightly elastic mass, fixed, not tender, and the size of a grapefruit. There was no reaction to old tuberculin. With these findings and a normal temperature, the preoperative dagnosis was either a solid ovarian growth in all probability malignant or an unusually firm ovarian cyst. At operation the omentum was found adherent to the uterus and right adnexa. The omentum was free and a large ovarian mass was found on the right side fairly adherent to the broad ligament, the posterior surface of the uterus, and the rectum. The abscess was clamped off and removed. It was about the size of a grapefruit, filled with thick greenish yellow pus. The pathological report stated that it was an ovarian abscess probably an infected corpus luteum cyst. Cultures of the pus from the abscess showed hemolytic streptococci. Convalescence was febrile for four days and then normal. A reexamination eighteen months later showed the patient in excellent health, the scar firm, and the pelvic contents normal. The absence of inflammation of the Fallopian tube was further corroborative evidence that the infection did not spread to the ovary from below. They were unable to discover the original source of the infection. It was highly desirable that similar cases should be studied and reported so that this condition might be established as a pathological entity. Such reports would clear up the question as to the frequency of this condition. In addition to the clinical interest and importance, the possibility of such infection of the ovary was not without sociological significance in the life of the patient.

Dr. HERMANN GRAD said that the reader of the paper had reviewed the various conditions that must be fulfilled before we could say that we had a hematogenous infection of the ovary and the case he reported showed these conditions, but he did not think that was a final proof that the case was one of hematogenous infection of the ovary. Clinically there seemed no other possibility of another source of infection and yet it did not do to jump at conclusions, because a broken down neoplasm contained streptococci. The presence of these organisms might have been accidental and might not be responsible for the pathological changes found in the neoplasm, the patient not having suffered with a systemic reaction. This was an interesting problem and needed to be worked out for its scientific value.

Dr. WIENER, in closing, said he did not mean to give the impression that he agreed with what Rosenow claimed as a result of his experiments. He spoke of hematogenous infection as the cause of microcystic degeneration of the ovary, while the speaker did not believe that microcystic degeneration as commonly found, was due to hematogenous infection. As regards the case reported this evening, it must be admitted that the route of infection was still open to question. The subject had not been thoroughly worked out as yet. However, here was an intelligent girl, a virgin, who was very carefully examined and in whom there was nothing to indicate the probability of an infection extending from the external genitals, no redness of the urethra, or of the Bartholin ducts, no signs of irritation of the vaginal or cervical mucosa; no history or evidence of the introduction of a foreign body. As regarded Dr. Grad's contention that the finding of the streptococci might have been a fortuitous occurrence in a broken down cyst—two months previously this patient had been treated for acute appendicitis. When she came in her temperature was normal, the abscess being well walled off. But there were active hemolytic streptococci in the abscess; that was by no means a chance finding. The abscess burst while they were removing it and some of the pus escaped. The wound was drained but the patient's temperature was 103° to 104° Fahr. for several days after the operation. The infection was therefore an active one. It was impossible to prove with absolute scientific accuracy that this was a hematogenous infection. One could only say that in all probability it was. The hematogenous source of an ovarian infection could not be proven with the accuracy of a scientific experiment in any woman who had a patent vagina.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE STATE MEDICAL BOARD OF THE ARKANSAS MEDICAL SOCIETY.

Little Rock, May 14 and 15, 1918.

ANATOMY.

1. Describe the femur.
2. Fully describe the shoulder-joint, and give overlying structures.
3. Briefly describe the heart; give blood and nerve supply.
4. Name muscles of the arm, giving origin of each.
5. Name branches of axillary artery.
6. Describe the minute anatomy of the kidney.
7. Where and into what does the great sciatic nerve divide?
8. Name the spinal nerves entering into the formation of the plexuses, and state the plexus with which each is connected.
9. What structures pass through the jugular foramen?
10. Describe the urinary bladder of the male, and give its relations.

PHYSIOLOGY.

1. (*a*) Describe a pulse wave. (*b*) How is it maintained?
2. What change takes place in the diameter of the chest in inspiration and expiration?
3. What change takes place in the blood as it passes through the kidneys?
4. (*a*) What is the per cent. of solids in normal urine? (*b*) Name the organic solids of urine.
5. Differentiate between special sensations and common sensations.
6. Describe the formation of lymph.
7. What would be the result, should you place a man on a vegetable diet free from sodium chloride?
8. Describe the condition of rigor mortis.
9. How is heat production regulated in the human body?
10. Give five physiological functions of the liver.

CHEMISTRY.

1. Give difference between a chemical union and a mixture, with an example of each.
2. Name five elements and give symbols.
3. Define an element.
4. Describe two laboratory processes for producing hydrogen.
5. Describe chlorine.
6. Na plus water equals what? Give equation.
7. Describe Marsh's test for arsenic.
8. Give two tests for albumin in urine.
9. Give formulæ for the following: Calomel, salt, sulphurous acid, nitrous acid, zinc sulphate.
10. Complete the following: $Zn + HCl =$

MATERIA MEDICA.

1. Give incompatibilities and action of argenti nitras.
2. Give dose and action of jalap.
3. (*a*) Give the vulgar name for physostigma. (*b*) Name its alkaloid.
4. How would you prepare a solution of mercuric iodide for intramuscular injection?
5. Give properties and action of oleum theobromatis.
6. (*a*) What is the source of iodum? (*b*) Give its incompatibilities and action.
7. (*a*) What is the source of strychnine. (*b*) Give its action.
8. (*a*) What are glucosides? (*b*) Give an example.
9. (*a*) How are fluid extracts prepared? (*b*) What is the relative strength of fluid extracts?
10. What is the source of arsenic? How is arsenic trioxide made?

THERAPEUTICS.

1. Explain the therapeutic effect of quinine in treatment of malaria; outline proper dose.
2. Give physiological action of nux vomica; name its principal alkaloid; state its use and dose.
3. Name two drugs that increase the hemoglobin of the blood; give dose and use.
4. Discuss general principles that should guide one in the therapy of typhoid fever.
5. Discuss precautions to be taken in the use of mercury in treatment of syphilis.
6. Give uses of iodine, and name preparations most prescribed internally.
7. Give therapeutic use of: (*a*) Salol; (*b*) sodium phenosulphate.
8. What are the physiological effects of digitalis; and in what diseases would you administer it?
9. Discuss treatment of acute rheumatic fever.
10. Give physiological action of atropine; and give its therapeutic use.

ANSWERS.

ANATOMY.

1. The *femur* or high bone consists of a shaft, and an upper and lower extremity. The shaft is expanded above and below, is curved and twisted, and is concave behind and convex in front. Its anterior surface is smooth, and its posterior surface is rough and prominent; the linea aspera extends from the trochanters along the middle third of the bone, bifurcating and diverging at the lower end to enclose the popliteal space. The upper extremity presents the head which articulates with the acetabulum, the neck which connects the head with the shaft, the great trochanter which is a large, rough, quadrilateral eminence and gives attachment to several muscles, the digital fossa to the inner side of the great trochanter, the lesser trochanter, the anterior and posterior intertrochanteric lines, and the tubercle of the femur at the junction of the neck with the greater trochanter. The inferior extremity is large and presents the external and internal condyles of which the external is shorter and broader and the internal is longer; between these condyles is the intercondyloid notch; and between the condyles, in front, is the trochlea which is a smooth surface and articulates with the patella.

2. The *shoulder-joint* is an enarthrodial joint formed above by the glenoid cavity of the scapula and below by the head of the humerus. Its ligaments are glenoid, coraco-humeral, and capsular. The glenoid surrounds the edge, deepens the glenoid cavity, and is continuous above with the long head of the biceps tendon. The capsular ligament, extensive and loose, arises above it from circumference of glenoid cavity behind the ligament, is attached below to the anatomical neck of humerus, and is pierced by tendons of two or three muscles. The coraco-humeral, or accessory, is a fibrous band which extends obliquely downward and outward from the coracoid process to the anterior part of great tuberosity, strengthening the capsular ligament. A *synovial membrane* lines the joint, and forms the bursa under the subscapularis. It is reflected round the tendon of the biceps, and lines the bicipital groove. The *nerve supply* is from the circumflex and suprascapular nerves. The *arteries* are branches of the anterior and posterior circumflex, and the suprascapular.

The *muscles in relation with the joint*, are: above, the supraspinatus; below, the long head of the triceps; in front, the subscapularis; behind, the infraspinatus and teres minor; internally, the long head of the biceps. The deltoid covers the joint in front, behind, and externally.

3. The *heart* is located obliquely in the thorax, between the lungs, and enclosed in the pericardium. A line from the lower border of the second left costal cartilage (one inch from sternum) to upper border of third right costal cartilage (half inch from sternum) represents the *base line;* the *right side* will be a line drawn from right side of upper limit to seventh right chondrosternal articulation; the *lower limit* is a line from this last point to the apex (in fifth intercostal space three and one-half inches from mid-line); the *left side* from left end of upper border to left of apex. The heart lies opposite the fith, sixth, seventh and eighth dorsal vertebræ.

Its walls consist of muscle fibers, with some connective tissue to which many of the fibers are attached.

The heart is divided by a septum into a left and right heart; and each side is further divided into an upper chamber (auricle) and a lower chamber (ventricle), connected with valves so arranged that circulation of the blood only occurs in one direction. In the *right auricle* are the Eustachian and coronary valves; the former is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice. In the right auricle are also found the openings of the superior and inferior venæ cavæ, coronary sinus, foramina of Thebesius, the auriculo-ventricular opening, the fossa ovalis, annulus ovalis, tubercle of Lower, and the musculi pectinati. In the *right ventricle* are the tricuspid and semilunar valves; also the columnæ carneæ, chordæ tendineæ and the auriculo-ventricular opening and the opening of the pulmonary artery. In the *left ventricle* are the mitral and semilunar valves, the columnæ, chordæ tendineæ, and the aortic and auriculo-ventricular opening. The heart is about 5 x 2½ x 3½ inches, and weighs about ten ounces. It is supplied with blood by the right and left coronary arteries. The nerve supply is from the superficial and deep cardiac plexuses, and from the vagus and sympathetic system.

4. The *muscles of the arm*, are: Deltoid, subscapularis, supraspinatus, infraspinatus, teres minor, teres major, coracobrachialis, biceps, brachialis anticus, triceps, subanconeus.

The *deltoid* arises from outer third of clavicle, acromion and spine of scapula; the *subscapularis*, from the subscapular fossa; the *supraspinatus*, from the supraspinous fossa and fascia; the *infraspinatus*, from the infraspinous fossa and fascia; *teres minor*, from middle part of dorsal surface of axillary border of scapula; the *teres major*, from dorsal surface and inferior angle of scapula; *coracobrachialis*, from coracoid process of scapula; *biceps*, from coracoid process, and from upper margin of glenoid fossa of scapula; *brachialis anticus*, from lower half of front of humerus; *triceps*, from infraglenoid tuberosity of scapula, from posterior surface of body of humerus at upper part, and also below the groove for the musculospiral nerve; *subanconeus*, from lower part of triceps.

5. The *branches of the axillary artery* are: Superior thoracic, acromial thoracic, long thoracic, alar thoracic, subscapular, posterior circumflex, and anterior circumflex.

6. "The kidneys are invested by a thin, fibrous capsule, which is attached by connective tissue and bloodvessels. It is easily stripped off. On making a longitudinal section through a kidney the glandular structure will appear to be divided into two portions: (1) the outer or cortical portion, for the most part occupying the surface, except at the hilus; (2) the medullary portion, consisting of a number of pyramids separated from one another by cortical substance. (1) the cortical substance occupies the greater part of the gland, being 1/3 to ½-inch in depth at the surface, and extends into the center of the gland between the pyramids; the cortical portion between the pyramids being termed the columns of Bertini. It is of a light red color, and more or less distinctly striated in appearance, the striations being due to the interlobular vessels and bundles of straight tubes which pass from the base of the pyramids to the capsule. The Malpighian bodies may be seen as reddish points, or sometimes standing out from the surface like grains of sand. The bundles of straight tubes are called the medullary rays. (2) The medullary portion occupies the center of the gland, and consists of eight to twelve of the pyramids of Malpighi. These pyramids are surrounded at their bases and sides by cortical substance, while their apices project into the dilated portion of the ureter at the hilus, which forms the pelvis. The pyramids are divided by Ludwig into two layers or zones—the boundary layer and the papillary layer. The boundary layer has well-marked striations, this appearance being due to the vasa recta, and to the bundles of tubules passing down the pyramid toward the papilla. The papillary layer is of a more uniform dull red color. The Malpighian bodies are about 1/120 inch in diameter, and are situated in the cortical portion between the medullary rays. They consist of a tuft of capillary vessels in a capsule formed by the dilated end of a urinary tubule. The tuft is termed the glomerulus, the membranous envelope Bowman's capsule. The glomerulus receives an arterial twig from an interlobular artery, and its efferent vein joins a plexus which surrounds the convoluted tube before joining an interlobular vein. Bowman's capsule consists of a homogeneous membrane, lined by flattened epithelium, and joins a convoluted tube by a constricted neck. The convoluted tubes commence as capsules in the cortex, twist upon themselves several times, then on joining a medullary ray, take nearly a straight course. They have a distinct lumen, and are lined by short columnar cells, narrower at the lumen than at the basement membrane. The outer part of the cell is distinctly striated; their inner part is granular. They have a well-marked nucleus. The convoluted tubule passes into a spiral tubule of Schachowa, which is situated in the medullary rays; these are more or less spirally arranged, the epithelium is the same as in the convoluted tubes. The spiral tubule on entering the boundary layer becomes narrower, and forms the descending loop-tube of Henle; the epithelium is here flattened, with a prominent nucleus. The ascending loop-tube, which has re-entered the boundary layer, is wider than the descending, and is lined by a layer of polyhedral fibrillated cells. It next enters the cortex, is somewhat narrower and wavy, and passes upwards in a medullary ray. It then leaves the medullary ray and forms an irregular tubule. Its shape is irregular, its lumen small, and its epithelium consists of short, columnar, fibrillated cells. The irregular tubule passes into the second convoluted tube, closely resembling the first convoluted tube. It then passes into a more or less wavy collecting tube before it joins a straight collecting tube. The collecting tubes commence in the cortex and pass through the boundary layer into the papillary layer, are lined by columnar or cubical epithelium, and have a distinct lumen."—(Ashby's *Notes on Physiology.*)

7. The great sciatic nerve divides into the internal and external popliteal nerves, at about the lower third of the thigh; but the division may take place at any point between the sacral plexus and the lower third of the thigh.

8. The first four spinal nerves enter into the formation of the *cervical* plexus; the fifth, sixth, seventh, and eighth cervical and the first thoracic nerves enter into the formation of the *brachial plexus;* the first four lumbar nerves enter into the formation of the *lumbar plexus;* the fourth and fifth lumbar, first, second, third, fourth, and fifth sacral, and the coccygeal nerves enter into the formation of the *sacral plexus.*

9. *Structures that pass through the jugular foramen:* Inferior petrosal sinus; lateral sinus, meningeal branches from the occipital and ascending pharyngeal arteries; and glossopharyngeal, pneumogastric and spinal accessory nerves.

10. The *male bladder* is a musculo-membranous pouch, situated in the pelvis, behind the pubes and in front of the rectum. It has a superior surface, antero-inferior surface, two lateral surfaces, a base or fundus, and a summit or apex. It is retained in its place by the two anterior ligaments, two lateral ligaments, and the urachus; there are also five false ligaments formed by folds of the peritoneum. Internally, on the floor, is the trigone, between the openings of the two ureters and the urethra. The anterior part of the bladder is uncovered by peritoneum, and is in relation with the triangular ligament, the symphysis pubis, and the pubo-prostatic ligament. Above it is covered with peritoneum and is in relation with the rectum and small intestines. The base is in relation with the rectovesical pouch, vasa deferentia, and seminal vesicles, all of which separate it from the rectum. It is supplied by the superior, middle, and inferior, vesical arteries; and the pelvic plexus of the sympathetic, and the third and fourth sacral nerves.

PHYSIOLOGY.

1. "Each contraction of the left ventricle gives rise to a dilatation of the systemic arteries, with an increase of blood pressure, which is propagated as a wave toward the smallest arteries. This wave is the *pulse-wave.* The pulse-wave travels through the arteries at the rate of 30 feet a second—that is, about thirty times as fast as the blood-flow—so that it is about one-tenth

of a second later in the radial and posterior tibial arteries than in the aorta. The pulse-wave can be accurately investigated by means of the sphygmograph, an instrument which consists essentially of a button or pad, which is adjusted over the artery, a lever which amplifies the movements of the button, and a moving slip of smoked glass or paper, upon which the lever traces a curve representing the pulse-wave. The pulse-curve, or sphygmographic tracing, consists of a nearly vertical up-stroke, which represents the rise of the pulse and corresponds to the expansion of the artery, followed by a more gradual down-stroke, interrupted by a second rise—the dicrotic wave—which occurs after the systole of the heart, and corresponds with the closure of the semilunar valves. Just before this there is a small predicrotic wave, due to the vibration in the arterial wall. It occurs during the systole. The dicrotic wave is more developed when the tension of the arteries is less than normal, and when the contraction of the ventricle is strong and sudden. The pulse-wave is entirely lost in the smallest arteries and capillaries, except when the former are very much dilated, when it extends to the capillaries, and may even become perceptible in the small veins."—(*Aids to Physiology.*)

2. In *inspiration*, the diameters of the chest are all increased; the vertical diameter is increased by the contraction and descent of the diaphragm, and the antero-posterior and transverse diameters are increased by the elevation and outward rotation of the ribs and the elevation of the sternum. During *expiration*, these diameters are all reduced.

3. In its passage through the kidney, the blood loses water, salts, urea, carbon dioxide, and extractives.

4. In normal urine, the percentage of solids is about four per cent. The *organic solids of the urine*, are: Urea, urates, hippurates, creatinine, oxalates, and extractives.

5. *Common Sensations* cannot be distinctly located in any organ or set of organs; such as hunger, fatigue.

Special sensations are distinctly associated with some definite part of the body, and give us information respecting matters outside our bodies; such as sight, hearing.

6. *Formation of Lymph.*—There are three main theories: (1) Ludwig's theory, or the filtration theory, coupled with osmotic changes between the lymph and blood; (2) Heidenhain's theory of lymphagogues; and (3) Starling's theory of the permeability of the capillary walls. The subject is summed up by F. A. Bainbridge as follows: "Lymph formation is not a secretory process, but is brought about by purely physical processes, namely, filtration and osmosis; and the factors concerned in its production are (1) the capillary pressure, (2) the degree of permeability of the capillary walls, and (3) the metabolic activity of the tissues. There is no reason to suppose that in health the permeability of the capillaries alters, and therefore the formation of lymph is increased chiefly by variations in the first and third of these factors."

7. A *vegetable diet with no sodium chloride* would cause loss of strength, with diminution of physical and mental vigor and power of endurance; resistance to disease might also be lessened; malnutrition and indigestion would also follow.

8. *Rigor mortis* is a condition of rigidity assumed by the muscles after death. It is supposed to be due to the coagulation of the myosinogen. The muscles lose their irritability and pass into a condition of contraction. Heat is evolved, carbon dioxide is given off, and the muscles become acid in reaction due to the development of sarcolactic acid. Rigor mortis usually sets in first in the muscles of the lower jaw, face, and neck, then in those of the thorax, abdomen, upper extremity and lower extremity. It usually lasts for from twenty-four to forty-eight hours, and disappears in the same order as the onset.

9. The normal body temperature is *regulated* and *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Heat is given off from the body by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

10. *Five physiological functions of the Liver.*—(1) glycogenic function, (2) formation of urea, (3) formation of bile, (4) production of heat, and (5) production of antithrombin.

CHEMISTRY.

1. When *chemical union* occurs, a new substance is formed possessing distinct characteristics of its own; and these properties may be very different from those of the substances which enter into the chemical union. In the case of a *mixture*, the component substances still possess the characteristic properties which they had before entering into the mixture.

2. Sodium, Na; potassium, K; silver, Ag; sulphur, S; hydrogen, H

3. An *element* is a substance from which we cannot obtain other substances.

4. Hydrogen may be prepared by the action of dilute sulphuric acid on zinc; or by the action of potassium or sodium on water:

$$Zn + H_2SO_4 = ZnSO_4 + H_2$$
$$Na_2 + 2H_2O = 2NaOH + H_2$$

5. Chlorine is a greenish-yellow gas, with a penetrating odor, and is very irritant to the respiratory tract. It has a great tendency to combine with most of the other elements. A candle burns in chlorine with a faint flame and a thick smoke. In the presence of water it is an active bleaching and disinfecting agent.

6. $Na_2 + 2H_2O = 2NaOH + H_2$. That is, sodium plus water equals sodium hydroxide plus hydrogen.

7. *Marsh's Test for Arsenic.*—This test depends on the fact that arsenic hydride is formed when nascent hydrogen acts on a compound of arsenic:

$$H_3AsO_3 + 3H_2 = AsH_3 + 3H_2O.$$

A small flask fitted with thistle funnel and a delivery tube, as for the production of hydrogen, is used; pure zinc and hydrochloric acid are introduced, and after a short time the hydrogen is ignited. It is advisable to cover the flask with a cloth before igniting the gas, as an explosion may happen unless the air has all been driven out. If the materials are pure the hydrogen flame gives no deposit upon a piece of cold porcelain brought into it, but commercial zinc usually contains arsenic. When the purity of the gas is proved, a little solution of arsenite may be poured down the thistle funnel, which will produce a more rapid evolution of gas, and the flame will become larger and perceptibly colored. A piece of cold porcelain depressed upon the flame will be covered with a deposit of metallic arsenic. The films of arsenic are metallic looking in the thicker places, brownish near the edges; they are easily volatilized by heat, and dissolve in solution of bleaching powder. A portion of the glass tube from which the gas is burned should be heated to redness; the gas decomposes and a deposit of arsenic appears on the tube, which may be identified in a similar way, or may be converted into crystals of oxide by cautious sublimation in an open tube.—(Fisher's *Elementary Chemistry.*)

8. *Two Reliable Tests for Albumin in the Urine.*—"The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture and again filtered."

I. *The Heat Test.*—"The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin is present a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3."

II. *Heller's Modification of the Nitric Acid Test.*—"Place in a test-tube a layer of HNO_3 about 2 c.c. in thickness; then, with a pipette, carefully float upon the surface of this a layer of the urine in such a manner that the liquids do not mix. If albumin be present a

cloudy ring appears *at* the point of juncture of the two layers, the borders of the cloud being sharply defined. A cloudy ring may be formed by the presence of an excess of urates, but in this case it is not *at*, but *above*, the point of juncture of the layers, and its upper border is not sharply defined, but fades off gradually."—(Witthaus' *Essentials of Chemistry.*)

9. Calomel, HgCl; salt (sodium chloride), NaCl; sulphurous acid, H_2SO_3; nitrous acid, HNO_2; zinc sulphate, $ZnSO_4$.

10. $Zn + 2HCl = ZnCl_2 + H_2$.

MATERIA MEDICA.

1. "*Incompatible with silver nitrate* are: Acetates, alkalies, alcohol, antimony salts, arsenites, bromides, carbonates, chlorides, chromates, creosote, cyanides, copper salts, ferrous sulphate, glucose, hypophosphites, iodides, morphine salts, oils, manganous salts, organic substances, phosphates, sulphides, sulphates, tartrates, vegetable astringent infusions and decoctions."—(Potter's *Materia Medica*, etc.)

Action of Silver Nitrate: It is an astringent, hemostatic, irritant, caustic, irritant, and tonic. It stains the skin.

2. The *dose of jalap* is 15 grains.

The *action of jalap* is that of a hydragogue cathartic; it stimulates the intestinal glands to increased secretion, and is sometimes diuretic.

3. The vulgar name for physostigma is calabar bean. Its alkaloid is eserine or physostigmine.

4. *Mercuric Iodide for Intramuscular Injection.*—

℞ Hydrargyri iodidi rubri.....gr̄iv
Olei olivæ.....ʒij M.

Sig: Ten minims to be given as an injection once a day. The dosage may be increased to 20 or 30 minims.

5. *Oleum theobromatis* is a yellowish-white solid, with a faint but pleasant odor and a taste like chocolate; it is readily soluble in ether and in chloroform. It is a nutrient and emollient, and is also used to make suppositories.

6. *Iodum* is *obtained* from the ashes of seaweed. It is *incompatible* with alkaloids, ammonia, metallic salts, mineral acids, and oil of turpentine.

Action of Iodine: "Irritant, disinfectant, parasiticidal, absorbent, alterative. On the skin its first effect is a brownish discoloration. Its irritant action, while slow, is both penetrating and prolonged, and by repeated applications pronounced counter-irritation can be produced without deep destruction of tissue. As a result of its local application small quantities are absorbed. Minute doses have a tonic effect upon the stomach; large doses may cause gastroenteritis. In animals it has been known to cause fatty degeneration of the heart, liver, and kidneys. Its chief effects after absorption are due to its action on the thyroid gland, and the symptoms produced by its continued administration resemble those resulting from the use of thyroid extract. It is excreted chiefly by the kidneys, but also in the saliva, perspiration, bronchial secretion, and milk."—(Wilcox's *Materia Medica.*)

7. *Strychnine* is obtained from the Strychnos nux vomica and Strychnos ignatia.

Action: Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension, stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes.

8. *Glucosides* are organic, vegetable substances, which on being treated with heat or a dilute mineral acid yield glucose and some other substance. *Examples:* Amygdalin, digitalin, salicin.

9. *Fluid Extracts.*—"These are concentrated liquid preparations of vegetable drugs, containing alcohol either as a solvent or as a preservative, and bearing a uniform relation to the drug used so that *one mil* of the fluid extract closely represents the activity of *one gramme* of the air-dried and powdered drug of standard quality. They are of four classes: (*a*) Those made with a menstruum of alcohol or a mixture of alcohol and water by the usual process of percolation. (*b*) Those made by using glycerin or an acid in the extraction; the first menstruum contains the glycerin or acid and the second a mixture of alcohol and water for completing the exhaustion of the drug. (*c*) Those made by the process of fractional or divided percolation. (*d*) Those made by infusion and percolation with boiling water, alcohol being added to the concentrated liquid as a preservative."—(Wilcox's *Materia Medica.*)

10. Arsenic is chiefly derived from the arsenical sulphides orpiment and realgar, and from arsenical iron pyrites.

Arsenic trioxide is made by roasting the native sulphides of arsenic in a current of air.

THERAPEUTICS.

1. "In *malaria* quinine is practically specific. In tertian or quartan malaria, about two or three hours after a large dose of quinine, the parasites in the red cells can be seen to have lost their ameboid motions, and they soon become granular and die. The quinine acts most strongly on the forms just breaking into spores and on the free-swimming organisms; and as these are present in the blood about the time of the chill, the quinine, on account of its rapid absorption and rapid excretion, is best given just at this time. Fifteen grains (1 gm.) may be administered just before, during, or after the chill, and it should be followed by 5 grains three times a day for one or two months. In malarial regions quinine is taken in large quantities (1 dram) as a prophylactic; it is rapidly excreted. There is much evidence to show that it does reduce the number of cases in a malarial community, and does not seem to do any harm to the takers."—(Bastedo's *Materia Medica*, etc.)

2. NUX VOMICA. *Physiological action:* Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension, stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes. *Therapeutic indications:* As a general tonic or bitter; in indigestion, cardiac depression, impaired peristalsis, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, some forms of paralysis, chorea, epilepsy, neuralgia, alcoholism, and urinary incontinence.

Its principal *alkaloid* is strychnine.

The *preparations* and *doses* of nux vomica and its alkaloid are: Nux vomica, one grain; extract of nux vomica, one-quarter of a grain; fluid extract of nux vomica, one minim; tincture of nux vomica, ten minims; strychnine, one-sixty-fourth of a grain; strychnine sulphate, one-sixty-fourth of a grain; strychnine nitrate, one-sixty-fourth of a grain.

3. *Two drugs that increase the hemoglobin of the blood:*—Iron and arsenic trioxide.

Iron is used in cases of chlorosis, and secondary anemias. Dose, reduced iron, one grain; or Blaud's pills, two pills (each pill containing one grain of ferrous carbonate).

Arsenic trioxide is used in cases of primary pernicious anemia. Dose, one-thirtieth grain; or three minims of Fowler's solution.

The administration of *iron* in anemia and especially chlorosis often rapidly increases the amount of hemoglobin and the number of red corpuscles. It is useless in pernicious anemia; and of little value, if any, in the anemia of leukemia, exophthalmic goiter, and Hodgkin's disease. In common forms of anemia which are secondary to some special cause, such as hemorrhage, lead poisoning, malaria, scurvy, etc., the removal of the cause is essential to recovery, but the use of iron salts is often of great service in aiding the latter. . . . To restore the amount of hemoglobin and the number of red corpuscles, small doses of reduced iron or of the carbonate, or some one of the combinations with vegetable acids, are usually the most serviceable. In chlorosis better results are often obtained from combinations of iron with strychnine or arsenic than from iron alone.

Arsenic is used to some extent in the treatment of diseases of the blood as anemia, and especially in diseases of the blood-making organs which are designated

as primary anemia, including leukemia, exophthalmic goiter, Hodgkin's disease, and pernicious anemia. In chlorosis, as well as in instances of anemia, where iron disagrees with the patient or proves unsuccessful, it is considered a valuable agent. In these disorders the efficiency of iron is at times much increased by the addition of arsenic.—(From Wilcox's *Pharmacology and Therapeutics.*)

4. *General treatment of typhoid fever:* "As soon as the nature of the disease is recognized the patient should be confined to bed. The room should be large and airy, and provided with efficient means of securing thorough ventilation. The temperature of the room should be maintained between 65° and 70° F. The bed-pan must be used from the beginning until convalescence is well advanced. The stools and urine should be rendered innocuous before being thrown out. This may be done by treating the evacuation with twice its volume of a 1 per cent. solution of chlorinated lime or a 5 per cent. solution of carbolic acid, and allowing it to stand in a covered vessel for two hours before emptying it into the closet. Soiled clothing should be thoroughly boiled. The *diet* should be liquid or semisolid, unirritating, and easily digestible. Milk alone (6 ounces every four hours) does not supply the required number of calories (2,500-3,000), but, as a rule, it should form a large part of the diet. It may be given diluted with lime water, or as buttermilk, malted milk, kumiss, junket, or ice cream. Among the other suitable foods may be mentioned raw or soft-boiled eggs, chicken jelly, milk toast, strained oatmeal gruel, potato puree, tea, coffee, cocoa, fruit juices, wine jelly, and custard. Beef tea and broths may be harmful. In the event of digestive disturbances the diet should be restricted for a time to whey or albumin water. Water, plain or flavored (lemonade, soda water, etc.), should be given in large amounts between the feedings. When the first sound of the heart becomes weak and the pulse dicrotic, alcohol is usually indicated. From 4 to 8 ounces of whisky or brandy may be given in the twenty-four hours, the amount being determined by the general effect. The *cold bath* or the *cold pack* affords the best means of controlling fever and preventing the development of severe nervous symptoms. It may be employed every three or four hours, when the temperature is 102-5° F. or over. Hemorrhage, signs of perforation, menstruation, and great prostration are contraindications."—(Stevens' *Practice of Medicine.*)

To *prevent* the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food. Prophylactic vaccination of exposed persons has been advised.

5. *Precautions to be taken in the use of mercury in treatment of syphilis:* "During the course of mercury, the patient's general health and habits must be carefully regulated; alcohol is forbidden, exercise limited, and strict instructions are given as to keeping the teeth and gums clean. An astringent mouth-wash containing alum and chlorate of potash should be ordered, and it may be necessary to remove or stop diseased teeth, but the dentist must, of course, be informed of the nature of the case. To minimize the risk of throat and mouth trouble, it is wise to stop all smoking for at least six months. The dose of mercury required varies in different individuals, being increased in robust people, and diminished in those who are weak or unhealthy. It should always be pushed until mild physiological effects are produced in the shape of slight tenderness of the gums, but salivation of the patient is undesirable. Full doses are usually required for four or five months, followed by a milder course, which should extend till the end of the first year. It is advisable, however, to insist on a three-months' course of mercury twice a year for two and a half or three years."—(Rose and Carless' *Surgery.*)

6. *Iodine* is *used* externally (as tincture) as a disinfectant, also as an irritant, counterirritant and parasiticide. Internally it has been used as an antiemetic. The iodides have been used in syphilis (third stage), pleurisy, pericarditis, rheumatoid arthritis, aneurism, asthma, and in hydrargyrism and plumbism. Iodine is used externally and internally in some cases of goiter.

The preparations and doses of iodine and the iodides are: Iodine, one-tenth of a grain; compound solution of iodine, three minims; tincture of iodine, one and a half minims; potassium iodide, seven and a half grains; sodium iodide, seven and a half grains; ammonium iodide, four grains; strontium iodide, seven and a half grains; zinc iodide, one grain; diluted hydriodic acid, fifteen minims; syrup of hydriodic acid, one dram.

7. *The therapeutic uses of salol* are: As a disinfectant, in inflammation of the mouth and pharynx, in cystitis, as an intestinal antiseptic in typhoid fever, in muscular rheumatism, in intestinal indigestion and fermentation, in cholera.

The therapeutic uses of sodium phenolsulphonate are: As an antiseptic and antipyretic, in typhoid fever, septicemia, puerperal fever, the exanthemata, and malignant endocarditis.

8. DIGITALIS. *Physiological action:* It is a gastro-intestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels, and causes a rise in blood pressure, it also acts as a diuretic. *Therapeutic use:* Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is *contraindicated* in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc.

9. *Treatment of acute rheumatic fever:* "The patient must be kept absolutely at rest in bed. He should lie between blankets, not sheets, and should wear a flannel night-gown. The diet should consist of milk, diluted with mineral water; if it does not agree, chicken broth may be given. In convalescence it may be more ample, but red meat should be sparingly used. Salicylate of soda, or salicin, is the specific remedy, the latter being the less depressant form. In severe cases, the salicylate should be given in doses of gr. xx every two hours until the pain is relieved, thereafter every four hours till the temperature falls, and then less frequently and in smaller doses, its withdrawal being gradually accomplished. In less severe attacks gr. xx every four hours may suffice. Should the salicylate disagree, other salicyl compounds (oil of wintergreen, aspirin) may be used. In the view of the majority, the salicylates shorten the course, protect the heart, and lessen the liability to relapse; but some still prefer the alkaline treatment, in which case large doses (℥iss) of sodium bicarbonate are given every three hours. The amount is lessened when the urine becomes alkaline. If the pain in the joints is severe, they should be fomented, and the limb should be put upon a splint. A lotion of carbonate of soda and laudanum, or a liniment of methyl salicylate, may give relief; and morphine is sometimes required at first. Hyperpyrexia should be treated by the cold bath.—(Wheeler and Jack's *Handbook.*)

10. ATROPINE.—*Action:* Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

Therapeutic indications: For the relief of pain, to dilate the pupil, to check secretions, for diarrhea, for asthma, for shock and collapse, for colic of all kinds, for delirium, for epilepsy, chorea and migraine, for paralysis, for cough, in constipation, in chorea, spermatorrhea, or cystitis.

NOTES ON THE SURGICAL TREATMENT OF EMPYEMA.*

By W. WAYNE BABCOCK

LIEUTENANT COLONEL, M. C., U. S. A.

Pleural effusions so prevalent in the various army camps and cantonments during the past winter have been associated with a mortality so high as to demand special consideration. The effusions for the most part have occurred after measles and croupous pneumonia, and have given an average mortality of 31 per cent., but in some camps it has reached 65 per cent., 84 per cent., and even 100 per cent. The microorganism chiefly responsible, and giving unusual features to the epidemic is the *Streptococcus hemolyticus*.

Three periods characterize the epidemic as to time and virulence: First, the period of November, December, and January, which marked the greatest intensity of the disease. At this time a typical clinical picture is that of a patient convalescent from measles, who, after exposure, develops thoracic oppression and dyspnea. There is slight lividity, deepening into cyanosis, with evidence of a rapid outpouring of serum into one or both pleural cavities and perhaps also into the pericardium and peritoneum. Loud, moist rales are heard over the chest, and the respiration grows progressively more difficult and more superficial. The effused fluids teem with streptococci, and at times the microorganism may be recovered from the circulating blood. In from 24 to 72 hours the patient is dead. At the post mortem the lungs show large areas of congestion and edema. There is some purulent bronchitis and peribronchitis. In some cases the lungs are necrotic. The effusions in the serous cavities are seropurulent. The process is so rapid that a definite pneumonic process or true pyothorax usually is not found. After the onset of the disease the patient is usually too weak to stand any formidable operation, and has an infection too generalized to be benefited by simple aspiration. Should the patient, however, survive the early stages of infection, consolidation of lung, pulmonary abscess, and purulent infection of the various serous cavities may occur.

The second period of streptococcus infection as to virulence began the latter part of February and extended into April. While serious, the epidemic had lost its intense virulence, and the patients lived long enough to develop other lesions. Usually the patient did not develop the acute and tragic symptoms, and the serous pleural effusions progressed after from several days to one or two weeks to a purulent stage. Pneumonic consolidations and pulmonary abscesses not infrequently occurred, and metastatic effusions in other large serous cavities or in the joints. In the joints the results varied from complete disorganization to spontaneous subsidence with only moderate stiffness. At times there were pyemic manifestations, including multiple subcutaneous abscesses of mild virulence containing streptococci, and promptly healing after simple incision, as in typhoid fever. The presence of streptococci in the blood, while ominous, was not always of fatal import.

In April the third stage of the epidemic was observed. While the *Streptococcus hemolyticus* was still the predominating organism, a pyothorax was the chief lesion, but it usually was amenable to treatment, and death was rare.

The virulence of the epidemic, therefore, bore a direct ratio to the coldness of the months and the microorganism also apparently progressively attenuated as the epidemic advanced. Not only were the infections more severe and more fatal in the early winter months, but they were more enduring and more resistant to treatment, so that empyemas starting in the early winter not infrequently continued to drain until spring or summer, while those beginning late in the epidemic often closed first. In part this may be the result of better management, but irrespective of the treatment it is evident that the late cases were much less virulent and much more amenable to treatment than those of the early months of the epidemic. Not only this, but patients bore the larger thoracoplastic operations or decortications much better in the spring than in the winter. Statistics on methods of treatment which do not take into consideration the rapid attenuation of bacterial virulence as the epidemic progressed have little value. To this attenuation we may largely ascribe the wide diversity of surgical opinion. Thus we find in some camps where surgeons operated promptly during the first part of the epidemic, and operated less promptly and less frequently as the epidemic progressed, the opinion that early operation was responsible for the high mortality. Again, if, during the early weeks of the epidemic, few operations were done and prompt surgical treatment was instituted only after post mortems had revealed the large pleural effusions present in similar cases, the surgeon was prone to argue that the mortality was due to delay in operating. If the surgeon aspirated early in the epidemic, and began to reset ribs at a later stage when the virulence had declined, he concluded that aspiration was dangerous and a cause of bacteremia. If, on the other

*Presidential address delivered at the annual meeting of the American Therapeutic Society at Richmond, Va., June 7 and 8, 1918.

hand, the surgeon resected first and then later, on account of the overwhelming mortality, began to do more aspirations and to practise delay, he concluded from his increasingly favorable results that aspiration was the safer and better procedure.

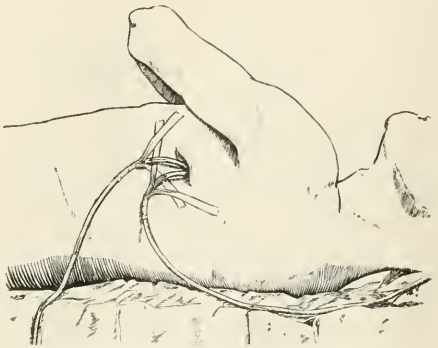

Fig. 1.—Arrangment of tubes for Carrel-Dakin treatment of empyema. Skin incised under local anesthetic and two rubber tubes introduced through an intercostal space by means of a large trocar.

Unfortunately, our results in handling these pleural effusions have been too poor, our experience too limited. to permit fixed conclusions, but the plan thus far worked out is as follows:

1. For sudden serous effusions, with cyanosis and marked dyspnea of streptococcic origin, no treatment or simple paracentesis to relieve pressure temporarily. As showing the early virulence, of eight cases treated by aspiration or puncture drain seven died, one patient recovering after a single aspiration of a small quantity of thick pus.

2. *Dakin Irrigation.*—For acute serous or seropurulent effusions a single thorough irrigation with Dakin's fluid, under local anesthesia by 1 per cent. procaine, is used. Two rather stiff rubber tubes, size 18 to 25 F, are introduced into the cavity. A large, short trocar is employed, the tubes being carried into the cavity through the cannula. The skin is incised and the trocar introduced into the cavity at two points. The tubes are introduced separately and the cannula withdrawn, leaving the tubes in place. One tube has its outlet dependent and under fluid, the other is attached to a sterile funnel containing warm Dakin's fluid. Without permitting air to enter, the irrigation is continued with a pressure head of fluid not greater than 10 inches until the faint tint of the permanganate color of the Dakin fluid is observed at the outlet. The chest is now emptied, the tubes withdrawn, and the puncture openings dressed with gauze wet with dichloramine-T in chlorcosane. The later management of the case depends upon the possible return of the fluid and on its character. Repeated *x*-ray studies are of especial value in association with aspiration and the usual methods of physical examination. Of four cases treated by a single antiseptic irrigation one died and two recovered without further operation.

3. *Continuous Carrel-Dakin Treatment.*—Empyemas with creamy or curdy pus are treated by introducing under local anesthesia by means of a large trocar, stiff rubber tubes, size 30 to 36 F., with a terminal and one lateral opening. The tubes are graduated with indelible ink before sterilization, so that their depth of introduction may always be evident. They are passed through the same or contiguous intercostal spaces to a depth just sufficient to place the lateral opening well within the cavity. One tube is fastened to a Dakin reservoir, the other empties under solution in a container placed under the bed (Fig. 1). The tubes are fastened to the chest wall by adhesive plaster (Fig. 2). The height of the surface of the Dakin should not be more than 10 inches above the chest cavity. Every two hours from 50 to 200 c.c. of the Dakin solution is permitted to enter the pleural cavity. This should not produce pain and often will not arouse the patient if asleep. About 1/5 or 1/4 more fluid escapes than enters the chest, due to the aspirating action of the drainage. As a rule the tubes remain nearly water tight where they pass through the chest wall. The method is therefore very cleanly and convenient and only a small dressing is required. Under the treatment, pus and curdy masses are dissolved, there is no odor, and the drainage becomes clear and gelatinous. In the early days of the treatment there may be rises in temperature, but the patient should rapidly improve and show a marked increase in appetite and comfort, with gain in weight. If the treatment is painful or the drainage imperfect the tubes should be promptly readjusted, reintroduced at some new point, or discarded in favor of some other form of treatment. Excessive pressure in instillation or improperly placed tubes may cause pain, extension of the pleural inflammatory process, or leakage into

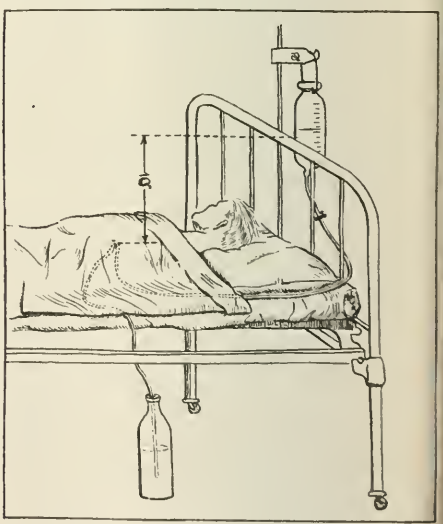

Fig. 2.—Showing arrangement of apparatus for Carrel-Dakin treatment of empyema.

the subcutaneous or muscular tissues with the possible production of an axillary or subpectoral abscess. Large tubes by pressure may also cause necrosis of adjacent ribs. To prevent leakage under the skin it is wise to make the skin incisio

distinctly wider than is necessary for the introduction of the tubes. The object is to sterilize the cavity, and the tube should be withdrawn as soon as clinical sterility is accomplished. A bacteriological count may be made by irrigating the cavity

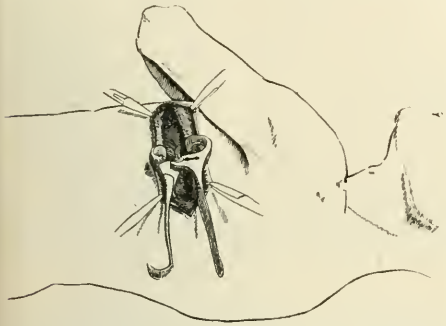

Fig. 3.—Exploratory thoractomy, with rib spreading. Long intercostal incision and rib spreader in place. Seven centimeters of separation may be obtained.

with one per cent. sodium thiosulphate solution to neutralize the Dakin fluid; cultures are made from the last washings that pass from the drainage tubes.

Of eleven patients treated in this manner, two died, six were healed without other forms of operation, one required secondary thoracostomy, one a costatectomy, one a pulmonary decortication. Five of the patients have returned to duty and one is healed awaiting discharge; three having had secondary operations are now nearly healed. This mortality of 18 per cent. compares well with the average mortality of 32.4 per cent. obtained in treating 37 cases by various methods. The duration of the irrigation in these cases was from two days to four months. After removal of the large irrigation tubes it was found wise to insert small 4-mm. Dakin tubes in the openings and to continue Dakin irrigation for two or three days to sterilize the tube tracts. The use of dichloramine-T in these openings has not been found so valuable.

4. *Double Tube Drainage.*—Simple tube drainage without Dakin irrigation, the large stiff rubber tubes being introduced by means of a trocar as above described, and carried below the level of fluid in a receptacle on the floor under the bed is usually curative in the empyemas of children. In one of our early cases healing occurred in one month from this treatment alone. As a rule it is not sufficient in adults.

5. *Exploratory Operations.*—Cases with persistent cavities and poorly draining sinuses are explored either through a long intercostal incision, with spreading of the ribs, or by costatectomy or thoracoplasty. By a simple rib spreader (Fig. 3), the ribs may be separated for six or seven centimeters, sufficient to introduce the hand and to explore the pleural cavity thoroughly. The ribs are held apart by a special rib prop (Fig. 4). In many cases, especially in old dense walled cavities, it is more satisfactory to resect freely the ribs overlying the sinus or cavity. If necessary the lung is freed or decorticated. The wound is left freely open pending sterilization by the Dakin method, or partially closed with a large valve-tube drain. It is especially important to remove bismuth paste which prevents the obliteration of cavities and is a cause of gingivitis and other toxic conditions, bits of necrotic bone, foreign bodies, to separate localizing partitions and to freely open all poorly draining pockets. These extensive operations are best carried out under properly administered gas-oxygen anesthesia.

6. *Secondary Closure* of large thoracic cavities left after operation for empyema has been successfully carried out by Tuffier by first sterilizing the cavity by the Carrel-Dakin method, then excising the wound margins and mobilizing the skin edges, which are united without drainage. The method converts the chest cavity into a pneumothorax, which is supposed to close spontaneously. Tuffier reports success in 16 out of 23 cases. In five of our cases one was successful, two partly successful, two failed. In none of our cases with a large cavity was the complete closure successful. Our present tendency is to unite the skin and underlying muscles, leaving an adequate drain.

7. *Pulmonary Fistulas* present special surgical problems. With a fistula communicating with a bronchus, irrigation or Dakin treatment cannot usually be employed. There may be a single opening, following a lung abscess or area of necrosis, or the surface of the lung may be like a sieve from multiple small openings. Often the character of the external sinus does not reveal the form of fistula. Roentgen ray studies after bismuth injection give much aid but involve the risk of filling the bronchi and alveoli with the insoluble paste. In most cases operative treatment is desired.

We have considered the following methods of closure:

(*a*) Suture of the opening with or without resection of a wedge-shaped portion of adjacent lung tissue.

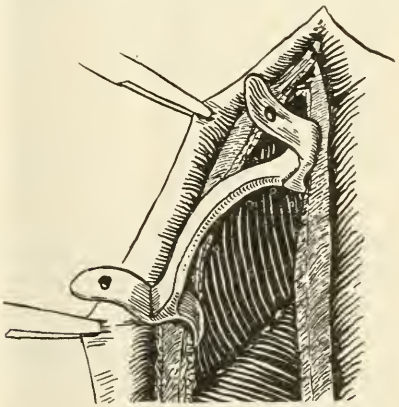

Fig. 4.—Simple rib prop for holding ribs apart in exploratory thoracotomy.

(*b*) Occlusion of the opening by suturing the adjacent lung tissue to one edge of the deep wound in the chest wall. This may be immediately effective and permit the prompt resumption of irrigation of the empyema cavity.

(*c*) Plugging of the opening by suturing into it or over it a flap taken from the adjacent soft tissues. This may consist of mobilized parietal pleura, skin, or other soft tissue. A flap of muscle is usually preferred.

(*d*) Closure of the opening by means of a purse-string suture, introduced about its margin.

(*e*) Apposition and adhesion between the surface of the lung and overlying chest wall obtained either by mobilizing the lung or by a thoracoplasty. Usually several ribs are resected and the lung is mobilized by freeing its edges and dividing adhesions. The wound is then closed except for a large valvular tube drain. We have seen extensive subcutaneous emphysema follow the lack of an air vent. In these cases the affected lung is distended during expiration and the air leakage occurs during this

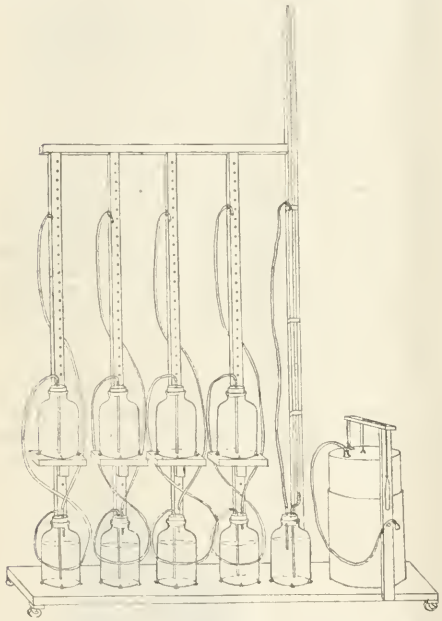

Fig. 5.—Improvised apparatus for graduated expiratory exercise. A simple manometer made of a bottle and glass tubing and a spirometer shown to the right.

time. In the operation of pulmonary decortication, surface vesicles are often opened and it is possible multiple fistulæs may follow this operation. Usually, however, such damage to the cortex of the lung is rapidly repaired.

(*f*) *Delay.*—Many fistulas heal in time by a process of granulation after free opening and drainage of the empyema cavity. The last word has not yet been uttered as to the best treatment of pulmonary fistulæ.

Of great importance in the after treatment of empyema is proper exercise. Patients should be encouraged to be out of bed as soon as possible after operation, and special exercises should early be undertaken. We found the use of a simple improvised spirometer and manometer of value. The interest of the soldier is excited by the daily records made, and the figures give him an incentive to progress with the treatment. Competition and association are of great value in this work. By blowing definite quantities of water from a lower bottle to a higher one, patients may be made to do a graded amount of work daily and a progressive increase in the distending force of the exercise obtained. Fig. 5 shows a simple apparatus which may be used by four patients at one time. It has been found much easier to develop and maintain interest by such an apparatus than by the usual Wolfe bottles. The patient is also encouraged to increase his chest expansion by exercise while sitting in a chair with fixation of one side of the chest, and by selected calisthenic movements. Finally he is permitted to do the heavier forms of manual labor; farming and gardening having especial advantages in developing the chest and in aiding to determine as to whether or not the soldier is fit to resume military service.

THE PREVENTION, DIAGNOSIS, TREATMENT, IMMUNITY AND CURE OF TUBERCULOSIS.

By OWEN PAGET, M.D. (Cantab.).

FREMANTLE, W. AUSTRALIA.

CAPTAIN, A. A. M. C.; HON. CONSULTANT, FREMANTLE PUBLIC HOSPITAL; MEDICAL OFFICER OF HEALTH, FREMANTLE AND DISTRICT, WESTERN AUSTRALIA.

THIS paper, the result of nearly five years' investigation into the subject of tuberculosis, is compiled from articles published in Australia and America.

I am happily much indebted to my former teacher, Professor Adami of Montreal, for valuable help and advice, and to Dr. Allen Thomas of New York and Dr. P. H. S. Hartley, C.V.O., of London, for kindly interest.

Practising for the most part as a surgeon, I was interested some years ago in discovering that many adults were unable to breathe efficiently through the nose. By "efficiently" is meant the power to breathe through the nose not merely for a few breaths, but constantly, and even during exertion. So many people appeared able to take perhaps two or three breaths through the nose, and were then forced to take the next through the mouth. Again others, either from inability or indifference, habitually breathed through the mouth.

Whilst this question of nose breathing interested me as a practitioner, in my capacity as Medical Officer of Health my attention was drawn to the occurrence of epidemics of a subacute form of pneumonia, which appeared at the period of our dust storms. In my further capacity as Area Medical Officer, *i. e.* medical officer for the examination of cadets aged 12 to 18 for their military service, I was surprised to find that, in spite of our perfect climate and the fact that the Australian child receives plenty of good food, the physique of the cadets was very indifferent, and their chests were often feebly developed and misshapen.

Incapacity for nasal respiration seemed, except in the case of adenoids, to be slurred over in textbooks on nasal surgery as something of only partial interest. It was relegated to the position of a symptom of such conditions as a spur on the septum or hypertrophied turbinates rather than regarded as a disorder in itself.

My attention once drawn to this frequent incapac-

ity, I found at length that, whatever its apparent cause, it could, except in the case of adenoids, be corrected by supporting or pulling outwards the lateral nasal cartilages. In other words, it was primarily dependent on weakness of the walls of the cartilaginous part of the nose, and such conditions as hypertrophies and deflections were really phenomena of secondary importance.

About the time that these subjects engaged my interest, there was considerable discussion in mining circles with reference to proposed drastic legislation for the protection of miners from miner's phthisis, and thus a further subject was added which intuitively linked itself to the others.

The occurrence of these varied problems caused me to attempt to discover if possible: (1) The reason of the poor physique of our cadets. (2) What are the effects of an incapacity to breathe through the nose? (3) Can pneumonoconiosis and allied disorders be prevented?

These three questions will be discussed in the following sections, and the conclusions they entailed will form the subject matter of the remainder of this paper.

The Effects Produced by Inability to Breathe Through the Nose.—As already stated, certain physical deformities of the face and chest are produced by rickets and obstructed nasal breathing. The importance of this will be more fully understood when attention is given to an aspect of the nose which heretofore has received very little consideration, namely, its action as a filter. Text-books on anatomy and physiology so persistently regard the nose as an organ of smell as to obscure the probabilities of its possessing other functions.

Examining the skulls of lower animals, especially in relation to the nose, the large proportion which this organ occupies of the total skull area is most striking. For example, in the hyena, the nose, irrespective of the soft parts, is equal to the combined volume of the mouth and brain. In some of the African deer the proportion the nose bears to the rest of the skull is enormous. But even more interesting are the size of the sinuses and the elaborate beauty of such structures as the ethmoidal cells and the turbinates. It is unreasonable to believe that this area, so large in proportion to the rest of that important structure, the skull, and with such elaboration of detail, is simply and solely to convey the sense of smell, and incidentally to warm and moisten air, which, in many countries, is already warm and moist enough.

A little careful consideration shows either that a large portion of the nose has no function at all, which is absurd, or it has functions which have not yet been investigated with sufficient thoroughness. Even in the human nose, which compares poorly with that of other animals, the area utilized for conveying the sense of smell is limited to the upper regions, and is small in relation to the total surface.

There is no need to emphasize that the human being develops better who breathes through the nose. Experience, common sense and intuition make this easy of appreciation without discussion.

Assuming that the next most important function of the nose after the sense of smell is to act as an organ to breathe through, to what extent does it explain the elaborate structures found in the organ?

To do this it is necessary to discover what exactly the air contains in addition to its moisture and gases. The word "impurities" embraces all these substances, and the form in which they exist is that of dust. Now, dust can be divided for descriptive purposes into (1) mehanical particles, (2) microbic elements. The object of this classification is to draw attention to the provisions made by nature in the nose for dealing with these distinctive entities. In some countries dust storms are a feature of the climate, but even in moister countries like England and France the amount of dust in the atmosphere, whether inside or outside the houses, is enormous.

Through the courtesy of Mr. Hamilton, president of the West Australian Chamber of Mines, I have had an opportunity to examine a man who, working daily in an atmosphere dense with mining dust and with his mouth covered by a handkerchief, was able to show the condition in the nose arising from such employment. On examination the hairs of the nostrils were clothed with dust. The right side of the septum, anterior to the turbinated bones, had fragments of conglomerated dust stuck to it. The left side had a considerable cake covering the same position. The dust was easily detachable by blowing the nose. Other men examined who worked in a less vitiated atmosphere showed the hairs inside the nostril coated with dust, but the septum apparently clear. In only one case, that of a man with a large cavernous nose, did it seem as if the dust reached the turbinates. With this one exception, all the men examined denied having suffered from diseases of the nose, and further, they were apparently free from pneumonoconiosis.

In fact, what seems to take place is that inspiration, which is slow, deposits a certain quantity of dust inside the nostril, whilst expiration, which is more abrupt, blows it out again.

That the opening into the cartilaginous part of the nose is set at a considerable angle to the opening into the bony part must do much to prevent the carrying of dust particles as far as the turbinates; and even very light particles of dust are apparently filtered off by the cartilaginous part of the nose, for snuff makers are said to wear handkerchiefs over their mouths at their employment.

Although observation and experience show that the cartilaginous part of the nose is capable of filtering off the grosser impurities of the air, particles as buoyant as microbes must, for the most part, be carried on in the current, and this inspiratory current, after entering the bony part of the nose, passes along the upper chambers in the region of the ethmoid, superior and middle turbinates, and in some skulls in the lower animals there is apparently a bony division separating the inspiratory and expiratory channels.

Now, the effect of such structures as the sinuses, ethmoidal cells, and the turbinates is to break up and slow down the current, and this in such a way that probably in a well-constructed nose the whole of the air is brought into contact with living structures.

A study of the different structures of the nose when regarded as a respiratory organ is fascinating. It is not, however, my object to enter too much into detail, so I will merely draw attention to the utility of the sinuses. If one takes a cylinder of

cardboard and fastens a manometer tube, closed at its outer end, into the side of the cylinder, a working model of the nose and a single sinus is produced. If now one end of the cardboard cylinder is placed in the mouth and regular respiration takes place through it, there is no movement in the manometer tube unless the distal end of the cylinder is made smaller than the end held in the mouth. By experimenting in this way it can be shown that the commencement of inspiration draws air out of the sinuses until such time as the pressure of the inspired air in sinuses and nose counterbalances. Expiration then forces the last of the inspired air into the sinuses, where it remains till the next inspiration. In this way inspired air is maintained a maximum time in contact with living tissues, and a real explanation is made why patients who inspire through the nose merely along the channel below the inferior turbinate, or again, people with very capacious noses, show a liability to tuberculosis, though less than do mouth breathers.

The cells covering the turbinates and lining the sinuses are for the most part furnished with ciliæ. It has also been demonstrated by experiment that they are capable of destroying microbes. The beautiful and elaborate nasal structures noticed in many animals now become intelligible. They represent a method not only of filtering off microbes, but of actually catching and destroying them.

But this is not the limit of their function. Stimulated by microbic destruction, they are able, as will be described later, to secrete antibodies internally.

It is now apparent how important it is that the nose be anatomically correct, and that it fulfill all its physiological functions. If the function of the nose for inspiration is annulled as a result of faulty development, then even such coarse particles as quartz dust are drawn directly into the lungs, giving rise to disorders grouped under the heading of pneumonoconiosis. But air free from grosser dust may yet be injurious, and if laden with tubercle or other bacilli it is inspired directly into the lung, it may here set up those processes grouped under the headings of the pneumonias and phthisis. On the other hand, if the air passes through the filter of the nose, the grosser particles are removed and the microbic elements are not only destroyed but actually turned to good account by their utilization in the production of antibodies, which serve to neutralize any microbes entering the system by other channels.

To summarize: The effects of an inefficient nose are pneumonoconiosis, the penumonias and tuberculosis.

The Prevention of Pneumonoconiosis, Tuberculosis and Allied Disorders.—Indiscretion in infant feeding, want of attention to adenoids, a slackness of observation and discipline in parents and teachers as regards the importance of nose breathing in children lead to the important functions of the nose falling into disuse, and in consequence our protection against dust-borne disease is inhibited, and mankind is attacked by pneumonoconiosis, tuberculosis and other disorders.

As already mentioned, more sensible attention to feeding in infancy improves the development of the face, and the advisability of operation for adenoids is so universally accepted as to need no further discussion.

But actualities are actualities, and the fact remains that a large number of people are incapable of breathing through the nose. Though abnormalities, such as spurs of the septum, deflections and hypertrophies may have to be corrected, it is certain that the commonest cause of incapacity for nasal respiration lies in the feebleness of the nasal muscles and cartilages. The usual type of nose expressing this condition is compressed from side to side.

The differences of racial type of nose, and the many reasons for mouth breathing, either from inability or indifference to nasal respiration, form a study in themselves. Especially is it difficult to understand the absence of nasal respiration in people with snub noses, or with the Mongolian type of nose. But even in these cases support of the cartilages relieves the condition.

The conventional type of nose of the consumptive is laterally compressed, and the study of the reasons for this appearance helps to a very large extent to understand other types. With the occurrence of adenoids and the impossibility of nasal respiration, there is a natural tendency for the cartilages and their attached muscles to atrophy from disuse, and further, as a result of the softness of the bony structures from injudicious feeding the face does not broaden out and carry the cartilages with it. Even when adenoids disappear, either from operation or atrophy, unless special education is given, the incapacity for nose breathing remains.

The explanation of this is as follows: The nasal cartilages are supplied with no less than twelve muscles to dilate them. If these muscles are incapable of action or merely enfeebled from disuse, then when inspiration draws the existing air out of the nose, causing thereby a negative pressure, the muscles are unable to hold open the cartilages, which become compressed toward the septum, and, as a result, nasal respiration is no longer possible.

This condition existing in youth is, I believe, one of the commonest causes of tuberculosis in latter middle life. Many people as they grow older lose the muscular power to support their nasal cartilages, and, in consequence, are attacked by tuberculosis. I have, however, seen a man of 72, engaged in laborious mining work, who, with very thin cartilages, yet maintained his nasal respiration. His nasal muscles stood out like steel bands.

Nasal respiration is dependent on the configuration and solidity of the nasal cartilages, the amount of fatty supporting structures, and perhaps most of all on the efficiency of the nasal muscles.

Experimenting with various mechanical contrivances for supporting the alæ nasi, and finding that each and all were defective in some respect or another, I was fortunate enough at last to discover in a surgical instrument catalogue a nasal prop invented by a Scotch throat and nose specialist.

They are made of silver wire, which should not be too thin, as otherwise it may cause a little soreness from pressure, and are supplied in four sizes, so as to be adapted to any type of nose. To use them they are slipped just inside the nostril, and act in a manner somewhat akin to a vaginal pessary. Invisible to other people, they are prevented from slipping out by the fold of skin and mucous membrane on the lower edge of the septum.

The proof that the right size is selected is shown

by the fact that when in place, without disfigurement, they make it possible to breathe through the nose without effort. As demonstrating the practical value of these appliances, I have patients who have worn them for three years and more. The majority, however, become careless of their use, lose and break them, and for this reason I advocate operative procedures.

A simple method of testing to what extent incapacity for nasal inspiration is dependent on weakness of the cartilages is to insert a blunt hook into the postero-external angle of each nostril, and to pull gently downward and outward. This causes a tautening of the cartilages, and if the patient is now told to shut the lips tight and take deep breaths through the nose he usually finds that he is easily able to do so.

The operation which I perform is founded on this simple fact, and consists in the excision of a crescentic piece of skin just beyond the external or posterior lower corner of the nostril. It is in a sense parallel to the natural curved line in this position. The width of the crescent at its widest part varies with the circumstances, but approximates to an eighth of an inch. The object to be achieved is to obtain permanently a similar result to that produced by the blunt hook. The wound is brought together by three horse-hair stitches, and Sir Arbuthnot Lane's cleft palate needles are used.

The accompanying diagram will assist to make the description more easily understood.

The benefits derived from the operation are:

1. It enables the patient to breathe through the nose, thus protecting him from pneumonoconiosis, and immunizing him against influenza, tuberculosis and catarrhal pharyngitis—in other words, all the disorders to which the mouth-breather is liable.

2. It improves the shape of the nose. This is easily tested in the first place by the blunt hooks or by means of the nasal props.

Disabilities are: The skin here is tough and filled with sebaceous glands. It is, therefore, a little liable to subacute wound infection, which does not, however, impair the ultimate result; possibly even strengthens it by forming a denser scar, which may, however, be a little noticeable for a short time. Later the scar seems to become hidden by the bolder outline assumed by the nostril. My patients have considered that they not only benefited in health, but that their personal appearance was improved. Suggestions have been made to me by surgeons that a simpler method would be to pass a silver wire subcutaneously from side to side in the region of the cartilaginous alæ, thus giving support to these structures. Such a procedure seems simple and feasible, but I have no personal experience.

At any stage, therefore, in life, it is in the power of the physician and surgeon to increase the resisting power of their patients against pulmonary disease. In earliest infancy unnatural methods of feeding are inadvisable. Later on, the necessity for children to eat hard though nourishing food should be insisted on, as not merely beneficial to the teeth, but also to the total welfare of the child.

With increasing age, if he learns to breathe through the nose, by operation, education and drill, the healthy development of the growing child is largely assured.

To forestall danger is to minimize risks, yet, happily, as will be shown below, even after disaster has occurred, it is possible by restoring the anatomical and physiological capacities of the nose, in addition to other treatment, to enable patients to regain and maintain vigorous health.

The prevention of mechanical irritation to the lungs, giving rise to pneumonoconiosis, is a certainty. The same can be said of microbic diseases, such as tuberculosis, when these theories are sufficiently understood.

The Actions and Reactions of Epithelial Cells.—In a former paper the statement was made that epithelial cells, *i.e.* the cells covering the turbinates and lining the nasal sinuses, produced antibodies in consequence of the microbes falling upon them. As this is a theory not yet accepted in pathology, I will describe the theoretical considerations, practical experiments and observations which have confirmed me in this belief.

When first engaged in investigating the nose as a protective organ against disease, I was limited entirely to a consideration of its utility as a filter, and by reference to the fact that its epithelium was able to destroy microbes. In my practice as a surgeon I was convinced that such conditions as catarrhal pharyngitis, the tendency to subacute pneumonia during dust storms, and also our endemic influenza could be ameliorated by enabling patients to breathe through the nose.

My first efforts to bring about nasal respiration, whether operative or by mechanical means, were but partial successes. In spite of this, there was often a marked improvement in the general health of the patients who had been under my care. I could not in honesty attribute this to my skill, and became certain that there was some unknown beneficial factor at work.

Further consideration seemed to point to the conclusion that even partial nose-breathing was capable of producing a certain degree of immunity. In other words, the inspiration of perhaps 50 per cent. of the microbes in the air on to the nasal mucous membrane was able to neutralize the harmful effects of the remaining 50 per cent. inhaled directly on to the pharynx and into the lung. This remained a vague belief until by chance a patient with advanced tuberculosis asked me whether there was any remedy which would benefit him. Unable to offer any relief, I suggested his drying his sputum in the sun and sniffing the dried powder up into the nose. I have treated many patients in this way, and for different reasons have often obtained but poor results, so it must be put down to good fortune that my first case responded in a most remarkable manner, and experimentally, at all events, made it certain that the nasal mucous membrane was capable of forming antibodies.

From this point onward through a long series of difficulties and mistakes in technique and judgment, I arrived at my present method of treatment by insufflations. This technique, which will be detailed in a subsequent chapter, is so simple that by a series of six insufflations of mgm 1/10th of tuberculin BE, it is possible so materially to benefit a patient's health that a definite diagnosis of tuberculosis can be made even in obscure cases. Thus, six insufflations onto the nasal mucous membrane

are sufficient to produce enough anitbody to improve such symptoms as loss of appetite, night sweats, tendency to headaches, and even temperature, thus showing that the antibody circulates through the system.

Even before arriving at this practical point, I had convinced myself on theoretical grounds of the capacity of epithelial cells to produce antibodies. Anticipating these theoretical considerations, it is worth while to follow another experiment, which, although it did not result in the recovery of the patient, yet showed that this epithelial capacity to form antibodies was something more than chimerical.

It seemed probable that if epithelial cells had curative properties against disease, it might be possible to utilize these in malignant disease. When serving with the French Army as Médecin-Majeure, a patient was sent to my hospital with what was said to be dysentery. On examination he was found to have a large, inoperable, malignant growth of the rectum. This patient was blistered two or three times a week on different parts of his body, and the fluid drawn up into a syringe was injected hypodermically. The case was described under the heading "Autosecretion in the Treatment of Cancer" in the MEDICAL RECORD, April 22, 1916.

It suffices here to give the report of Dr. Pettit, consulting surgeon in Paris, who saw the case on several occasions.

Décembre 16, 1916. "Lorsque j'ai examiné Piette le 15 Août 1915 j'ai constaté au toucher rectal une tumeur constituée par des saillies volumineuses reposant sur une base indurée et encombrant la lumière du rectum. Les saillies étaient dures, commes du cartilage, et le pulpe de l'index ne pouvait pénétrer au dessus de la tumeur ni-même s'engager dans le rétrécissement. L'état général était mauvais—amaigrissement, faiblesse. Je demandai une réaction de Wassermann qui fut négative. Je revois le malade le 16 Décembre 1915. Etat général bon. Forces en grand progrès. Embonpoint très satisfaisant. Au toucher le doigt pénètre facilement dans le rétrécissement maintenant plus large, et en dépasse juste la limite supérieure. Les végétations sont moins grosses et plus souples. La base indurée est beaucoup moins dure. Ces modifications sont particulièrement nettes vers la partie postérieure du retrécissement."

As already stated, this patient died later of what appeared to be a pernicious anemia. It suffices to show that experimentally, at all events, some action had been produced.

Referring back to theoretical considerations, it is patent that the epithelium of the skin and of the intestines is like that of the mucous membrane of the nose, constantly exposed to the action of microbes. It is easy to demonstrate that there is a marked difference in power to resist microbes between the epithelial cells of the intestine and the cells forming its serous coat. A mere puncture of the intestine will set up an acute peritonitis.

That the epithelial cells of the intestine have something more than a resisting power is made practical use of nowadays in the French Army, where immunity is produced by the oral administration of the products of the cultures of dead typhoid bacilli. In my paper, "Epithelial Function in Relation to Disease," published in the MEDICAL RECORD of September 18, 1915, I advocated this method on theoretical grounds as a protection against cholera.

Scarlet fever is perhaps the most striking example of the employment of the skin in the production of antibodies. In this disease, though the site of the original lesion is in the pharynx, it is not until the infective agents have been carried to the skin, and there by their reaction produced antibodies, that they are rendered innocuous to the host and the disease abates.

Really the importance of the epithelium, whether of the skin or bowels, has been empirically accepted by physicians from time immemorial. All people admit the improvement of health brought about by substances which stimulate the intestinal mucous membrane. It is the sheet anchor of our profession, whether prescribed in the hospital under the form of mistura alba, or to more wealthy patients in the form of fashionable spas. The frequent use of aspirin at the present day is due to its direct stimulating effect on epithelial cells, whether of the glands, such as the liver and salivary, or of the nasal mucous membrane or the skin. Perspiration, another empirical remedy of universal use, is an expression of the activity of the epithelium of the skin. Its presence or absence often decides the turning point of an illness.

Most vivid expressions of the utility of the epithelium in producing antibodies are to be seen in the erythemata of such affections as fish-poisoning, and again in the rashes of the exanthemata. From the time of the appearance of the rash we date the commencement of probable recovery. An abnormal rash, as in hemorrhagic measles is an expression of great danger, and every physician appreciates that a rash suppressed by chill or otherwise is a dangerous circumstance.

That nature definitely attempts to collect antibody, if such an expression is allowable, is shown by a simple observation and experiment. Most cases of tuberculosis suffer from frontal headache, which is almost certainly due to congestion of the frontal sinuses and neighboring structures. After insufflating tuberculin BE onto the ethmoidal region some half dozen times, there is almost invariably a marked decrease in the amount of headache complained of. Without too great a stretch of imagination, it is easy to believe that the nasal structures are congested to obtain antibody against tuberculosis, just as the skin is congested in scarlet fever to obtain antibody against that disease. In the case of the patient who does not breathe through the nose there is no antibody obtainable, since no bacilli have been deposited on the nasal mucous membrane, from whose destruction it may be produced. But if it is artificially supplied, then there is no necessity for the intense and unprofitable congestion.

A matter of great interest is whether different epithelia have specific action against certain diseases or whether all epithelia have similar reactions. My own opinion in this matter, unfortunately so far not sufficiently supported by experimental work, is strongly in favor of the specific action of certain epithelia against certain diseases. Thus, in tuberculosis, I believe that the nasal epithelium has very strong powers to form antibodies, that next in

importance comes the intestinal epithelium, and that finally the epithelium of the skin has only very slight, if any, antituberculous qualities.

Considering the enormous area of the skin and the slight effects it produces on the disease, as exemplified by the abortive character of the benefit received from night sweats, we may say that relative to the nose it is of small importance. That it is entirely negative I do not believe, because benefit is produced in tuberculosis by the employment of sun-baths. Again, to the reactions of the skin are probably due the haphazard improvements produced by tuberculin injected hypodermically.

Interaction between the epithelia is certain. One of the earliest expressions of benefit received from insufflations is a clearing or diminution in the muddy appearance of the skin, whilst the epithelial cells of the intestines have not without success been used to produce tuberculous antibodies by the oral administration of tuberculin.

In hot climates a chilling of the skin tends to bring on intestinal disorders, such as colic, dysentery and cholera; in cold climates it is the nose and lungs which are chiefly affected. Professor Adami in his "Pathology" expresses the law which governs this subject in the following words: "In infection the body is never involved as a whole. Coincidentally with the growth of the specific germs in individual organs there tends to be a reaction to and destruction of the same in other parts."

The Practical Application of These Theories.—It must be apparent that, whilst at the commencement of my research work my interest was engaged in such abstract problems as the prevention of pneumonoconiosis and the poor development of Australian cadets, by a gradual process my attention was focused on the prevention, treatment, and even cure of tuberculosis. If it was possible by sniffing sun-dried sputum or infinitely small doses of tuberculin BE into the nose materially to benefit and in some cases apparently to cure tuberculosis, surely this experimental work was capable of practical application.

It will not be out of place here to explain my reasons for the employment of tuberculin BE. It has been shown that my theories were of an essentially simple character. The deposition of tubercle bacilli on the nasal mucous membrane was sufficient to produce antibodies. My original experiments with sun-dried sputum were interesting in that the worst cases often did the best, which can now be explained by the probability that their sputum was richer in bacilli. However, the preparation of this snuff, whether by the sun or chemically, was revolting. Its employment three or four times daily was liable to irritate the nose. It was extremely variable in quality and haphazard in its effects.

Although I had early in my work found benefit to be derived from the sniffing of tuberculin BE into the nose, I yet determined to make a series of experiments with tablets of dead tubercle bacilli prepared for me by Messrs. Parke, Davis & Co. The disabilities of these preparations were as follows: (1) Variability of virulence dependent on the age of the growth. (2) The necessity for too frequent applications. (3) Their excessive bulk. (4) Their tendency to produce coryza and sore nose. (5) Their constant employment seemed to weary patients.

In the end I reverted to my original use of tuberculin BE, but as the result of kindly suggestions from Dr. T. P. Woo, late assistant medical officer at the Brompton Hospital, on more practical lines. The chief of these was the use of an insufflator to be described. The second was the abandonment of nasal props, which up to this time I had considered an essential of treatment. My present method is as follows:

A one milligram tablet of tuberculin BE is divided into 8, 10 or 12 powders, giving respectively doses of 1/8th, 1/10th, 1/12th of a milligram, and the dose decided on is insufflated into alternate nostrils three times a week or every second day. And, so far, no disabilities have been discovered arising from this treatment, except an occasional drying or watering from the nose, and more rarely a slight hemorrhage which can be safely neglected. I will detail its benefits:

1. Tuberculin BE is a more or less standardized preparation of dead and crushed tubercle bacilli, easy of absorption by the epithelial cells and with great capacities for the production of antibodies.

2. The smallness of its bulk prevents blocking of the sinuses.

3. It need only be employed every second day, and that in a different nostril, so that each nostril has four days' rest.

4. It further fulfills the following requirements essential for any treatment of real value in tuberculosis:

(*a*) It is easy of application by any physician. (*b*) It is not irksome to the patient. (*c*) It produces uniform results in all cases, of whatever type. (*d*) It is beneficial to all symptoms. (*e*) It is practical in that it can be employed alike with office or hospital patients. (*f*) It definitely enhances the resisting power against the disease. (*g*) There are no harmful complications from its use.

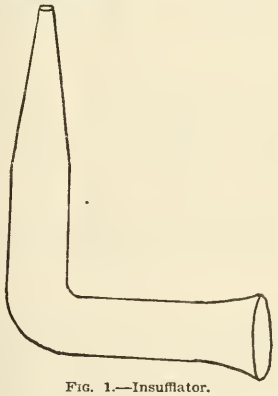

Fig. 1.—Insufflator.

The insufflator which I employ is of extreme simplicity. It consists of a glass tube bent to a right angle at its middle, and a rubber bulb syringe. The glass tube, as shown in the diagram, has certain important characteristics. Besides being bent to a right angle at its middle, the end which is passed up into the nose is tapered off somewhat to a point, so that it can be pushed up as high as possible into the nose. This is a matter of moment, as otherwise the powder may be caught on the hairs inside

the nostril or merely be deposited on some spur of the septum. A matter of extreme importance is that the point is directed straight upward and toward the frontal sinuses, and not backward toward the naso pharynx. This is best insured by the upright part of the tube outside the nostril resting against the upper lip. The other end of the tube is funnel-shaped in order that the powder when poured in shall not fall outside and be wasted. The rubber bulb syringe employed should be of a large size, like a Politzer's bag, and its nozzle should be preferably cone-shaped, so that it may perfectly fit any size of glass tube.

The method of procedure is as follows: The powder is poured into the tube, which is gently tapped to ensure it all lodging at an angle. The point of the tube is now inserted into the nostril by the patient, who is told to hold the tube firmly, so that at the moment of insufflation the point of the tube shall not be jerked and perhaps cause an abrasion inside the nose. It is, as already mentioned, all important that the point shall not be directed backward, but straight upward toward the frontal sinuses. The tube in position, and the powder in its place at the angle, the nozzle of the rubber bulb syringe is now inserted into the funnel end of the tube, and with a quick pressure the powder is blown into the nose in the region of the ethmoid and superior turbinate. I am accustomed to consider the insufflation satisfactory if it is felt by the patient in the region of the frontal sinuses or eyebrows.

A great advantage of this method is that each patient has his own tube, but that one syringe suffices for any number. This is of importance both in private and hospital work. The total time occupied by the procedure is about one minute.

During my work on tuberculosis, the reactions between the temperature and my method of treatment gave me much cause for thought, and occasionally even for alarm. At the present time I pay small attention to the temperature, which I know will fall in proportion to the improvement in other symptoms.

For purposes of explanation the effects on the temperature of the right, the too large and the too small dose will be described.

If in the case of a patient running a 102° evening temperature, an insufflation of mgm. 1/10 to 1/20 is given every day for four days running, the result is a rise in temperature of about 1° for two or three days, followed by a lengthy fall, so that on the fourteenth day the temperature stands at 1° to 2° lower than at the commencement of the treatment.

This is easiest shown on a diagrammatic chart.

Suppose now that mgm. ½ is insufflated on two to four following days. Then the rise will be higher and more prolonged, while the patient looks ill and hectic. The ultimate result is often excellent, the temperature falling 2° or more, but it is not a method which is advisable, especially in old people.

If mgm. ½ is insufflated four days running in a 99° type of case, then the excursion may rapidly rise to 103°, to be followed by a rapid fall in 24 to 48 hours, and the patient may feel much better. Again, I do not advise this, as it entails unnecessary shock.

With too small doses the result is either nil, or proportionate to the size of the dose.

My present method of treatment by tri-weekly insufflations does not produce graphic curves on the temperature chart, but the usual excursions become less marked and less frequent, and, as stated elsewhere, the temperature may be expected on the normal line about the end of the sixth week.

Puzzled for a long time by these effects of insufflations on the temperature, I venture now to offer a simple explanation. With a normal dose the production of antibodies is at its best. With excessive dosage the production of antibodies is temporarily inhibited, and direct absorption of tuberculin takes place. Finally, the production of antibodies reasserts itself, and an exceedingly good result may be produced. But in old cases the absorption of tuberculin which has already taken place may be too much for them, and lead to collapse.

Practical experience seems to show that mgm. 1/10 tri-weekly is the average dose. But in cases running a high temperature, and of hectic type, in which large quantities of tuberculous products are probably circulating in the blood, the possible danger of even temporarily adding to these products must be taken into account, more especially

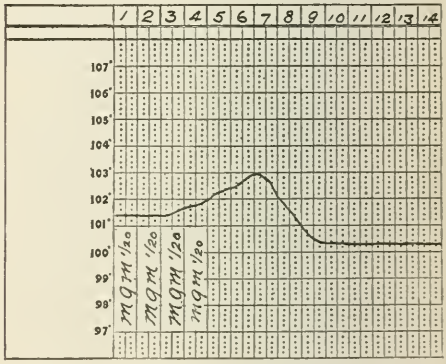

FIG. 2.—Chart showing temperature changes following insufflations of tuberculin B.E.

because the capacity to produce antibodies is perhaps diminished with fever. Therefore, a dosage which may be as low as mgm. 1/20 is used, proportionate to the general appearance of the patient, who is gradually brought to a condition in which larger doses can be wisely employed. It is more important to insure the patient's recovery than to be governed by a too rigid routine. In mild cases larger doses than mgm. ⅓ do not seem peculiarly beneficial.

That local reaction in the nose may cause an elevation of temperature is probably another phase expressing "Inhibition of production of antibodies, and direct absorption of tuberculin."

In the treatment of hectic and febrile cases the method adopted by my colleague, Dr. W. P. Birmingham, M.D., consulting physician to the Fremantle Hospital, W. A., will probably be found most suitable. He starts with 0.0001 mgm. tri-weekly insufflations, and when the patient ceases to improve increases to 0.001 mgm. When a standstill is again reached he increases to 0.01 mgm., and so on until the highest dose which the patient can stand without reaction is reached. This will be found to be about 0.1 mgm.

Insufflations should reduce temperature. If they cause a rise of temperature treatment is suspended for a few days and a smaller dose employed until toleration is established. Success is dependent on a maximum production of antibody and a minimal absorption of tuberculin. Even when excessive reaction is accidentally produced, ultimate benefit is always obtained, provided the treatment is temporarily suspended.

Actually, Dr. Birmingham considers that the physician's acumen and an appreciation of the patient's personal equation are of more importance than aiming for an increased dosage.

Explanations and Remarks.—It must not be considered that my experience in the treatment of tuberculosis is limited to the cases just noted. The number is probably nearer two to three hundred. But this series of cases definitely represents the results of a method of treatment with which I am satisfied. More important still, they are in the same sequence as they occurred in my practice, and not a mere collection of successful results.

I propose now to point out interesting features of these cases. Though perhaps not always recorded, it is certain that even in obscure cases of tuberculosis improvement will show itself at the end of a fortnight. In doubtful cases it may be advisable to continue the insufflations for another week. The importance of this is obvious. It supplies us with a simple and definite method of diagnosis.

The signs and symptoms which lead me to consider that the patient is better, and which confirm my diagnosis, are the following:

1. The patient's statement of his improved bien-être. However much physicians may dislike accepting such a statement from a tuberculosis case, it is, after all, the first question put to patients suffering from other diseases, and the reply, in conjunction with more definite facts, is worthy of credence.

2. Improvement in the insomnia, which so often accompanies tuberculosis, is definite evidence.

3. Improvement in appetite and digestion; this is a useful sign in those cases which have long suffered from peevish appetite, or who, on taking food, have been unable to digest it.

4. An improvement in the frontal headache from which so many tuberculous cases suffer.

5. An improvement in the appearance of the conjunctiva and the color of the skin. The former becomes whiter and clearer, the latter less muddy, and with a more rosy color.

6. In cases where the temperature is taken it may, if of the 99.4° variety in the evening, have settled down to normal.

7. There will very likely be some improvement in cough, and capacity for deeper breathing. The sputum may also be less in quantity and more mucous in character.

8. The determining factor of all is the willingness of the patient to continue treatment.

With this improved method of diagnosis it seems as if the number of tuberculous people in the community was enormous. They seem to drag on a sort of half-hearted existence, with visits to drug stores, the use of patent medicines, and the occasional advice of a physician.

If my work achieves nothing more than the early diagnosis of tuberculosis in the young chlorotic woman, or in the man who takes to drink because he feels his vitality failing, it will have helped many unfortunates and also the progress of medicine.

It is this early diagnosis of tuberculosis which is the important factor in the possible cure of the disease. The average case of tuberculosis is apparently not diagnosed by the average physician much under a period of two years or more, and usually not before distinct and permanent pathological changes have taken place. This is not due to want of knowledge by our profession of the prevalence of tuberculosis but to lack of a simple method of diagnosis.

If patients past the recuperative time of life, and with systems soaked—if such a description is permissible—with the causative factors and products of tuberculosis, are yet able to show marked improvement in their condition within a reasonable period of time, it is self-evident that patients in whom the disease has made but little headway will be so much benefited as probably to throw off the disease entirely.

It may be as well to make some practical suggestions at this juncture.

The majority of cases are seen by the general practitioner in the first instance, and it is not always easy for him to explain that he may suspect tuberculosis. Under such circumstances a little harmless subterfuge is not amiss, and the patient can be advised that the insufflations are primarily for the relief of headache or post-nasal catarrh, symptoms which so often accompany tuberculosis. If the patient's health is improved at the end of a fortnight or three weeks there is no difficulty in continuing the insufflations as a treatment.

Perhaps one of the most striking features of my series of cases is the improvement shown in patients past the prime of life, and who had been long affected with the disease. This indicates surely the small balance required to throw off tuberculosis. Another point is that with two exceptions the patients were able to carry on their ordinary vocations from the beginning without the relapses to ill health to which they were accustomed, or they were soon sufficiently improved to be able to do so.

This means that the treatment is essentially practical. A treatment must follow the usual custom of office attendance when rest in bed is not required.

With the gradual encroachment of the State into social and economic life, practical methods of dealing with disease become more important still. My method is equally applicable to sanatorium or dispensary.

In my studies on tuberculosis the character of this disease which has struck me forcibly is its fickleness. The physician can never feel confident as to the condition of his patient, and is perforce condemned to a most guarded attitude when questioned as to prognosis.

Now, it is not too much to say that my method of treatment will give the physician confidence. I do not say that he will always be right, since any one may be oversanguine, but it does enable him to feel that he has the case well in hand.

I pointed out above the definite influence that the insufflations have upon the temperature. I no longer employ the method of four insufflations on

following days for the purposes of treatment, though I occasionally use it in order to test the reaction of a patient.

A hectic case, though kept strictly in bed and at rest, is otherwise treated on the same lines and in the same manner as the chronic tuberculous.

This method, though it does not produce such graphic curves on the temperature chart, soon shows its steadying influence, and this modifying influence is concomitant with the improvement in appetite, cough, headache, and general malaise.

I am accustomed to regard six weeks as the average period of time required to bring the temperature to normal level, but the temperature at normal is no indication that the patient is fit to rise from bed. It is important, as in enteric fever, that a period of at least ten days be allowed with the temperature at normal, or very nearly so, before getting up.

The period of convalescence during which treatment is continued, occupies roughly a second period of six weeks. The total length of illness of a case of the hectic type is therefore three months. Even now I am not willing to believe that the patient is sufficiently well to resume his ordinary life, but consider a further three months' rest in country or sanatorium necessary, and this for the following reasons: It must be remembered that the average hectic case has been ill three or four years, or more, and that his lesions are often many and of a virulent type. So far as my experience goes, it is not possible to procure a large cumulative production of antibodies. The production can be enhanced by the employment of insufflations, and to such an extent as to enable the patient actually to throw off the disease, but this is a different matter to insuring that he will never relapse. He cannot apparently store up a supply for all future wants, though he is capable of keeping up a constant fresh supply. Now, this is very important practically, and explains much that is difficult to understand in tuberculosis.

Clinical tuberculosis is, after all, merely the expression of the resisting force being weaker than the invading force. I have developed this aspect of the question more fully in my paper, "Autosecretion in the Treatment of Cancer," MEDICAL RECORD, April 22, 1916, but it is worth while recapitulating here the main issues.

Every human is constantly attacked by tubercle bacilli, through either his lungs, his intestines, or his skin. At the same time he is as constantly resisting them by the production of antibodies. Suppose that the capacity for the production of antibodies falls 50 per cent. from disuse of such an organ as the nose, then such patient is liable to suffer from tuberculosis in proportion to the badness of his environment and the percentage of the fall in the production of antibodies. The patient, has, however, a resisting power in all his cells, and experience shows that with fresh air, good food, and rest, this resisting power may be so raised as to lead to a healing of the lesion by fibrosis.

If the lesion is not quite healed, but the production of antibody is just sufficient to neutralize its ill effects, it is obvious that the patient is in a position of equilibrium which is more or less unstable. For if the production of antibody is suddenly diminished then there is almost certain to be an exacerbation of the disease.

An illustration of this is the frequency of tuberculosis after measles. Here the production of antibody as a result of the catarrhal rhinitis is much diminished, and latent foci of disease have an opportunity of developing, since sufficient antibody is not produced to neutralize them.

The fickleness of tuberculosis is the expression of this constant fluctuation of ascendancy and lowering of capacity in resisting power. Though disease necessitates invasion, it is the lowering of resistance which brings on the attack.

My strong advocacy for a further three months' rest after the disease has been apparently cured by insufflations, can now be more thoroughly understood. It is necessary that all lesions should be completely healed before the patient can be allowed to be dependent on his production of antibody, even though this production has been restored to normal by attention to the nose.

Immunity and the Cure of Tuberculosis.—If sixtenths of a milligram of crushed and dried tubercle bacilli insufflated on to the nasal mucous membrane is sufficient to make a patient feel better who has suffered ten years from tuberculosis, it requires no effort of imagination to appreciate how beneficial to our welfare must be the daily deposit of tubercle bacilli on the epithelium of the ethmoidal cells and nasal sinuses.

As already stated in an earlier chapter, I have been surprised to observe the general improvement of health occurring in patients whose nasal inspiration has been restored. This is an experience, too, of most practitioners after operating for adenoids. That the capacity of our nasal mucous membrane for immunity is much greater than our requirements is shown by its powers for increased production, whenever it is stimulated thereto by means of insufflations.

It is advisable to differentiate, in tuberculosis, between relapse and reinfection. Relapse may be brought about, as described above, by an impossible demand on the virtues of the antibodies before existing lesions are healed. Reinfection cannot take place if nasal respiration is properly established, since the neutralizing antibodies are certainly in excess of requirements.

Immunity is the result of the anatomical perfection and the physiological activities of the nose.

It may seem as if I was too dogmatic on this point, but it is difficult to avoid being so. Five years' study of the relation of the nose to tuberculosis constantly proves to me how easily phenomena are explained which otherwise are inexplicable.

For example, a young patient has just left my office who has suffered all her life from chest troubles and malaise, undoubtedly tuberculous. Her health the last two years has been better, and she volunteered the statement that it was only within the last two years that she has been able to breathe through the nose.

If the cure of tuberculosis is discussed with physicians having a real clinical experience of this disease, they usually smile incredulously. This is no more than can be expected. Years of observation have shown them the futility of many panaceas. Further, even so-called cured cases of tuberculosis are at best cases in which an efficient fibrosis has taken place.

In spite of this I am convinced that the cure of tuberculosis can be raised from the realm of a theoretical idealism to a practical reality.

When the question of this cure is analyzed an initial insuperable difficulty arises. This is due to the fact that the average case of tuberculosis is not diagnosed until distinct and often permanent pathological changes have taken place. That this is so is shown by the circumstance that the period of malaise before a case is definitely diagnosed is apparently two years or more, depending on the skill of the physician consulted and the definite character of the symptoms and signs.

The initial necessity for the cure of tuberculosis is an easy method of diagnosis, and this is now possible.

The next requirement is a method of treatment beneficial to all symptoms, and that in every variety of the disease. This, too, has been attained.

And lastly, the patient cured, he must be able to maintain a constant production of antibodies, and thus a permanent immunity. It has been the chief object of this paper to show that nature in providing us with a nose has made special provision in this respect.

The cure of tuberculosis lies in an appreciation of the theories embodied in this paper, and a practical application of them by physicians, until such time as science and research shall further advance our lines of thought and methods of treatment.

Summary.—1. The nose is an organ of respiration as well as a conveyer of the sense of smell.

2. The nose is provided with hairs, glands, and other contrivances so that mechanical particles of dust shall not be inspired into the lungs.

3. The sinuses, ethmoidal cells, and superior turbinates are covered with an epithelium capable of destroying microbes. By their disintegration of tubercle bacilli they form antibodies which are secreted into and circulate within the system. The action of these antibodies is such that they can neutralize the ill-effects produced by tubercle bacilli existing elsewhere in the body.

4. While surgical attention can so restore the anatomical character of the nose as to enable us with certainty to prevent the occurrence of pneumonoconiosis, a restoration of its physiological functions definitely protects us against tuberculosis.

5. The cure of tuberculosis is dependent on (*a*) early diagnosis, (*b*) efficient treatment, (*c*) the restoration of immunity.

TYPES OF INFLUENZA IN INFANTS AND CHILDREN SEEN IN THE CURRENT EPIDEMIC.

BY LOUIS FISCHER, M.D.,
NEW YORK.

A CLINICAL study of a series of cases in the present epidemic, in infancy and childhood, has shown several distinct types.

Mild Type.—In many children we find a mild rhinitis or cough and a temperature ranging between 100° and 101°, with symptoms of slight malaise, anorexia, and at times catarrhal discharges from the bowels resembling colitis. These symptoms subside without any special treatment excepting rest in bed, a good dose of castor oil, and the substitution of barley water for milk feeding. As a rule these symptoms subside within three to four days. For this type of case the physician is rarely consulted.

These mild cases in which rhinitis or colitis exists, and in which the child is apparently in good physical condition, are the most dangerous to the community because they usually are unrestricted. Frequently a child with a temperature of 100° or little more is permitted to go to school and thus infection is disseminated. I have seen two children in one family suffering with a mild form of influenza, and a third child in apparently good health infected after three days with the most severe form of the disease complicated by pneumonia.

The cases most frequently seen begin with cough, hoarseness, croup, wheezing, and asthmatic breathing. The temperature ranges between 103° and 105°. There is extreme prostration and the children complain of muscular pains. The muscles of the arms and legs and the abdominal muscles seem to be affected. Trigeminal neuralgia, sciatica, pain in the lumbarsacral region, and supraorbital neuralgia have been noted frequently. The subjective symptoms are those of marked pain of lancinating character, continuous or intermittent. The children lie cramped at times, as though attempting to relax painful muscles. These intense pains form a very important symptom of this disease. Peripheral neuritis has been met with in over 33 per cent. of all cases.

Severe Type.—There is a sudden onset of symptoms. A child in apparent health in the morning will complain of a headache, have fever, nausea, and vomiting; if neglected it will within one to four hours be in a semi-stupor or a comatose condition. Convulsions are a very prominent symptom. Marked gastroenteric disturbances simulating acute milk infection in mid-summer have been frequently met with in this epidemic. One would almost suspect acute milk poisoning, and blame the milk as the etiological factor, were we not dealing with the influenza epidemic. Where the same feeding formula is continued, and fever exists for several days, the catarrhal or mucous discharges have frequently changed to those simulating dysentery of the Shiga type.

The following series of cases will give a better idea of the types met with:

CASE I.—*Gastric Type.* Leonard F., 10 months old, had been thriving, digesting normally, and seemed to

be in good health. On October 7 he began sneezing, vomiting, had loose bowels, and cried as though in pain. His temperature was 101°, pulse 124, and respiration 30. Diluted milk was ordered, and a dose of castor oil given, but the temperature continued to rise to 103°, pulse 140 and respiration 38. This was on the second day of illness. On the third day the temperature rose to 105°, pulse 150, and respiration 60. A slight cough developed. Vomiting persisted after each feeding. No medication was retained. There was no distinct evidence of consolidation. Barley water was ordered. Cold packs, later cold tubbing, were ordered to reduce the temperature. The infant seemed in intense pain, moaning or crying almost continuously, especially on being handled. He shrieked with pain when an arm or leg was moved. The head and neck were slightly rigid. The reflexes were exaggerated. On the fifth day the temperature, which had remained at 105°, gradually came down by lysis, dropping one degree each day. The vomiting and looseness of bowels continued almost one week. The only milk retained was dry milk, of which two tablespoonfuls to six ounces of hot water were given.

The interesting feature of this case was the sudden onset of vomiting and looseness of bowels, which lasted eight days in all, and ceased suddenly.

Hemorrhagic Type.—In another series of cases I have seen the hemorrhagic type in which purpuric spots, resembling bruises, were scattered over various portions of the body. Petechial areas were noted around the arms, at the elbows and knees, along the spine, and marked ecchymoses were noted in the roof of the mouth, on the gums, and in the conjunctival mucous membrane. The stools contained bright scarlet specks of blood, in some cases mixed with mucous, while in severer forms the liquid dejecta seemed to be pure blood. I have seen almost a pint of bloody liquid passed several times a day, so that the child was completely exsanguinated by the hemorrhages.

Case II.—*Pulmonary Type.* An unusually severe form of the infection was seen by me within the last few days in consultation with Dr. S. Clurman of this city. An infant, 15 months old, whose mother had just recovered from influenza, was ill five days when seen by me. There was a history of severe convulsions during the day. The temperature reached 105°, pulse 152, and respiration 72. There was marked cyanosis. Catarrhal colitis with mucous stools had existed for two days. There were moaning restlessness, and crying on being handled. The rhinopharynx was inflamed and there was a consolidation of the right central lobe, also a lobular area on the left side. The pupils did not respond to light and accommodation. The patellar reflex was absent on both sides. There was a marked Babinski (hyperextension of the big toe). On rotating the head, sternocleidomastoid rigidity was felt. The fontanel was depressed. A diagnosis of toxic pneumonia with meningismus was made. Prognosis doubtful.

Case III.—Another interesting case seen in consultation with Dr. Lowenkopf. The child, 18 months old, showed marked dyspnea, wheezing, and disturbed respiratory rhythm. An asthmatic bronchitis was made out and while intubation was thought of it was decided not to introduce a tube owing to the weakness of the heart and the profound toxicity. Marked improvement followed the giving of calomel and compound jalap powder until liquid evacuations were produced. Dry cupping of the chest seemed to relieve the wheezing. The diet was restricted to skimmed milk. The condition cleared up within five days.

Case IV.—*Fatal Type. Influenzal Pneumonia.* A girl, 16 years old, was infected by another member of the family. The first symptoms noted were a slight temperature of 101°, pulse 110, and respiration 28. The subjective symptoms were slight malaise and slight headache, but no constitutional disturbance. The diagnosis of mild influenza was made. Eliminative treatment with a restricted diet was ordered. The following day a slight improvement was noted. I did not see the girl on the third day. On the fourth day I was called again and found the temperature rising, more systemic disturbance, prostration, evidence of toxicity, slight headache muscular pains, respiration 36, pulse 128. Rhonchi were found scattered on both sides of the chest, but no evidence of consolidation. The temperature rose to 105° and it was impossible to lower it with antipyretics and sponging. A central pneumonia was diagnosed. The inflammation spread from lobe to lobe.

When seen in consultation with Dr. Walter B. James the diagnosis of influenzal pneumonia with marked toxicity was confirmed. Prognosis bad. On the following day there was an extension of the pneumonia, toxicity still more marked, pulse full, bounding and with high tension, and very irregular. There was marked cyanosis of the lips, face, and finger-nails. The expectoration was of the usual rusty character and the specimen submitted to Dr. Frederic Sondern was reported upon as follows: "The specimen consists chiefly of frothy blood-tinged serum and mucus with relatively little pus. Staining shows numerous pyogenic cocci including some in chains, believed to be streptococci; also a moderate number of small Gram-negative bacilli, morphologically similar to influenza organisms. Tubercle bacilli are not present."

The blood count showed a marked diminution of the white cells and a low polynuclear percentage. The blood did not show the clinical picture of a leucocytosis in pneumonia. In most cases the blood showed a marked leucopenia similar to that observed in typhoid fever. The polymorphonuclear neutrophiles were also very low. (In one of my cases here reported it was 56 per cent. during the acute lobar pneumonia. In the ordinary type of lobar pneumonia usually met with the percentage of polymorphonuclear neutrophiles is frequently 80 to 90.) The blood count in the case reported showed: Small lymphocytes, 24.0 per cent.; large mononuclear cells, 2.0 per cent.; polymorphonuclear neutrophiles, 56.0 per cent.; eosinophiles, none; mast cells, none; hemoglobin, 86 per cent.

Both diagnosis and prognosis were agreed to by Drs. Arthur Hollis and George Brown, who were called in consultation. Exitus lethalis on the sixth day.

Case V.—*Meningeal Type.* M. G., a girl, eleven years old, was seen in consultation with Dr. J. Tannenbaum. She had had a mild form of influenza lasting 4 days, with symptoms of cough and disordered stomach. Three days before my seeing the child she suddenly collapsed and was in a stupor, with temperature of 104°. She was pulseless when seen by Dr. A. L. Goldwater. There was no distinct evidence of meningitis. She recovered with restoratives and on the following day had a marked delirium. Two days later she was in a distinct coma lasting several hours. When seen by me she was apparently bright in the morning, and in a distinct stupor at the time of examination. There was marked rigidity of the muscles, the pupils responded sluggishly, the patellar and plantar reflexes were absent, there was marked hyperesthesia of the skin, and a tache cérébrale was present. The symptoms so resembled those of a tuberculous meningitis that it was decided to try a cutaneous tuberculin test and also do a lumbar puncture.

The von Pirquet test was negative. About 15 c.c. spinal fluid was aspirated. The fluid was examined by Dr. Frederic Sondern, who reported a normal fluid—no tubercle or other microorganisms present. The diagnosis of toxic influenza was made. The child made a complete recovery. The collapse previously reported was attributed to a toxic myocarditis. There was no nephritis present.

Of interest is the extremely toxic character of this influenza as manifested on the heart action, and especially its effect on the kidneys. In some cases seen by me a distinct heart block was noted, and marked evidences of toxic myocarditis existed twenty-four hours after the infection was noted. The secretory function of the kidneys was greatly diminished, and the urine in many cases showed marked evidences of acute renal congestion, in

which blood cells, albumin, and occasional casts were found. The quantity of urine secreted was greatly diminished, and it frequently was necessary to stimulate diuresis with copious warm draughts, besides giving diuretics which both supported the heart and assisted in stimulating the functions of the kidneys.

Digipuratum was frequently given for this purpose, likewise caffeine sodium benzoate in gradually increasing doses until its effect was manifested.

Lack of space prevents giving detailed therapeutics. Large doses of bicarbonate of sodium, one dram every hour, and colonic flushings of the same, seemed to do considerable good in the gastric type in which acidosis existed. In the pneumonic type camphor in oil, by hypodermic injection, was beneficial.

SOME EXPERIENCES WITH RADIUM IN THE TREATMENT OF PSORIASIS.

By Douglass W. Montgomery, M.D.,

San Francisco, Cal.

Psoriasis is a scaly disease which occurs in characteristic patches scattered over the cutaneous surface. It is undoubtedly owing to some constitutional disturbance, but what that disturbance is has hitherto successfully eluded all investigation. Although the affection is primarily due to some constitutional disturbance, yet individual lesions may be successfully treated and the annoyance occasioned by them eliminated for a greater or less length of time. The *x*-rays are among the most successful means of achieving this result, and the similarity in action between the *x*-rays and radium naturally suggests the latter remedy in a number of instances in which the lesions are few and localized. For example, a patient had an obstinate patch of psoriasis on the back of the wrist, and therefore obtrusively observable. A circular plaque of radium, covering the patch nicely, was applied. In due course the patch disappeared, but coincidently there sprang up about its border a number of minute patches, which, because of their arrangement, were even more noticeable than the original patch.

We had another instance in the person of a middle-aged woman who formerly had lues, in whom radium seemed to increase the eruption. She had an old patch of indurated psoriasis over the right patellar tendon. She was suffering severely from flatulent dyspepsia, and as this grew better the patch, which was being subjected to radium treatment, grew worse. No reason could be assigned for this; it simply was a fact. The radium seemed to stimulate into activity a patch which for years had been quiescent.

In another instance the patient was a young man, an athlete and sportsman, who had had patches of psoriasis for years, especially of the lower extremities. His skin at one time, on a wager, was entirely cleared by rest in bed and an exclusive milk diet. The eruption reappeared promptly on his resuming an active life and an adequate diet. This treatment, therefore, was futile excepting as done to win the bet, and as an experiment pointing to the real nature of the disease as being a nutritional one. In this patient's case *x*-rays topically, and regulation of the diet, excluding alcoholic drinks and luxuries, kept the skin reasonably free from eruption and permitted the enjoyment of adequate sports without comment. As the *x*-rays acted so well, it was thought that radium might act even better by shortening the time of treatment if nothing else. It did clear off the scales, but left in place of the patches a number of red, square and circular areas corresponding to the shape of the radium plaques, which were much more startlingly conspicuous than the original psoriasis patches, and which endured for many weeks, as such radium erythemas do. The patient wished no more of this treatment.

Psoriasis patches in the scalp should not be treated with radium because of the danger of the fall of hair, a danger common both to it and to *x*-rays. Patches of psoriasis and of seborrheic eczema, peculiarly obstinate, and often most annoyingly itchy, occur in the occipital region and nape of the neck, especially in elderly women. They are frequently amenable to radium when other means fail. Again, care has, however, here to be exercised that the hair is not knocked out.

A patient, while under treatment by radium for a synovial lesion of one of her fingers, and which by the way healed without incident, showed me a psoriasis patch of seborrheic type over the left elbow tip which was annoying because of the disfigurement when wearing a party dress. These patches are often peculiarly refractory to ordinary treatment. Under radium it cleared up *cito, tuto et jucunde.*

In conclusion, I would say that generally speaking, when radiant energy is desired in the treatment of psoriasis, *x*-rays are of more value than radium. The *x*-rays cover a larger surface, and do not leave the disagreeable red marks so frequent after the application of radium, and they seem to be at least equally effective in influencing the patches. In some situations, and when the patches are of the deeply indurated seborrheic type, radium seems to act better than the *x*-rays.

INTRAMUSCULAR INJECTIONS OF COLLOIDAL SULPHUR IN THE TREATMENT OF RHEUMATIC CONDITIONS.

By William Lee Secor, A.M., M.D., F.A.C.S.,

Kerrville-on-the-Guadalupe, Texas.

The first reference to the hypodermic use of colloidal sulphur in the treatment of rheumatism that I have been able to find occurred in an article which appeared in *Le Progrès Médical* for August, 1915. In the London *Lancet* of June 30, 1917, Major J. D. Comrie, M.A., M.D., F.R.C.P., published a paper entitled "The Treatment of Trench Rheumatism and Allied Conditions by Colloidal Sulphur."

Major Comrie has a wealth of material among the British soldiers in the hospital of which he has charge and gives a carefully tabulated report of this treatment in over sixty cases. After observing the results in this first series of cases he draws the following conclusions.

"(1) Intramuscular injections of colloidal sulphur are of the very greatest value in the treatment of subacute painful conditions in the muscles and

joints. (2) The most satisfactory course of treatment consists of an injection administered every second day for three weeks (10 injections), combined with rest and with massage on the intervening days. (3) In the greater number of subacute cases, lasting several months, complete recovery may be expected after three to five weeks from the commencement of the treatment. (4) This method is also very helpful in lingering cases of gonorrheal rheumatism. (5) It does not, however, take the place of salicylate of soda in relieving the pains of acute articular rheumatism."

On August 18, 1917, *Le Progrès Médical* printed an article by A. Bichon describing the effect of colloidal sulphur in rheumatismal affections of the eye, and in September of the same year A. Cawadias published a paper in the *Bulletin de l'Académie de Médecine* on the therapeutic action of colloidal sulphur.

Upon the strength of these papers the writer became interested in colloidal sulphur therapy. From a personal correspondence with Major Comrie I was enabled to obtain detailed information and suggestions as to the preparation of the colloidal sulphur for hypodermic use and as to the technique of its administration.

I found that there was not a suitable preparation on the market, so sent the detailed instructions to one of our reliable chemical companies, who very kindly prepared us a quantity in ampules. The method of preparation and directions for use as given by Major Comrie are outlined in the following paragraphs:

"The process used in the manufacture of colloidal sulphur, 1 in 1000, is as follows: Hydrochloric acid (10 per cent. HCl), 22 mils.; sodium sulphide (Na_2S, 9 H_2O), 5 gm.; sodium sulphite (Na_2SO_3, 7 H_2O), 2-6 gm.; whites of two eggs; sterilized water to 1 liter. Dissolve the sodium sulphide and sulphite each separately in 250 mils. of the water, mix together; add the white of egg and thoroughly mix. To this solution add the hydrochloric acid, diluted with 250 mils. of the water. The solution is then to be thoroughly mixed, warmed slightly, and sufficient sterile water added to make the volume 1 liter The solution after being carefully dialyzed to remove crystalloids, is then ready for use. Theoretically, the product should contain 1 in 1000 of colloidal sulphur. The chemical action is explained as follows:

$2Na_2S + 4HCl = 2H_2S + 4NaCl$, and

$Na_2SO_3 + 2H_2S + 2HCl = 2NaCl + 3S + 3H_2O$.

"Thus the sodium sulphite is reduced by the hydrogen sulphide produced from the sodium sulphide and hydrochloric acid. The presence of the albumin appears to prevent the aggregation of the sulphur into masses. In use the dose of 1 mil is rendered isotonic by the addition of 2 decimals of 5.5 per cent. saline solution mixed immediately before injecting.

"The dose with which I have been in the habit of commencing is 1 mil. (*i. e.* about 17 minims of the colloidal sulphur solution made up to 20 minims with the saline solution) injected into the painful area of muscle. If no reaction results, the dose may subsequently be doubled, the point of injection being slightly varied each time. In a course of ten injections the affected muscle receives into its substance approximately 1/50 gr. of nascent sulphur which is gradually absorbed."

I have used the intramuscular injection of colloidal sulphur in three cases with the results shown in the following reports. I am just beginning our study of this subject and the object of this paper is not to report what I have done, but rather to stimulate an interest in the investigation of a subject which apparently possesses some merit. This apparently premature report of my work is made with a view to getting others to work on this subject as soon as possible, for if it proves as efficient in our hands as it has in those of others it may be a valuable agent in the treatment of our returned soldiers who have contracted rheumatic conditions in the trenches.

Case I.—W. S., male, age 39, had had chronic rheumatism with recurrent attacks of iritis, neuritis, and myostitis over a period of seven years. Had had four severe attacks of iritis about a year apart. These each lasted from six weeks to two months and finally subsided, with very little permanent damage to the eye.

On October 25, 1917, a typical attack of iritis began in the right eye. Two c c. of the colloidal sulphur solution was injected intramuscularly on the night of the 25th and repeated on the night of the 27th. Examination of the eye on October 28 revealed no trace of the iritis. This patient has had no further trouble with iritis to date.

Case II.—A. A., female, single, age 30, referred by Dr. George B. Lee of Galveston, January, 1918. A typical case of acute rheumatic fever, which at the time I saw the patient was showing a tendency to become subacute or chronic. All proper attention had been given to removal of tonsils, affected teeth. examination of feces, etc. Ten intramuscular injections of colloidal sulphur were given, skipping one day between injections. Aside from local reaction we were unable to note the least effect. Patient did not show any improvement.

Case III.—W. S., same patient as Case I, on January 1, 1918, two months after treatment for iritis, applied for treatment of a chronic rheumatic condition which manifested itself in neuritis and myostitis showing exacerbations at times of weather change. This patient had had the tonsils removed, teeth radiographed, etc. Every other day 2 c.c. of colloidal sulphur solution was injected intramuscularly until ten in ections were made. There was slight local reaction, no apparent systemic reaction, and while the general condition of the patient seemed to be somewhat improved there was very little improvement in the rheumatic condition.

Sulphur and sulphides have had a reputation among the laity for many years of being beneficial in the treatment of rheumatism; whether it was used in the form of a bath at some famous sulphur springs or simply sprinkled in the shoes, there are those who are ready to testify to the good results. Whether the intramuscular injection of colloidal sulphur has some specific action on rheumatic conditions or whether it is simply another instance of the action of an injected foreign protein remains to be proven.

Abuse of Enucleation in Injuries of the Eye.—Poulard follows the lead of Dranoux in calling attention to the exaggerated fear of sympathetic ophthalmia. Enucleation is a simple but fearful remedy. Subsequent prosthesis is usually unsatisfactory, and one-eyed and disfigured employees are always at disadvantages. If operation is deemed necessary, anterior amputation will prevent loss of the other eye and secure a good cosmetic result. But we now know that sympathetic ophthalmia is a rare accident; it is doubtful if it occur once in 100 injuries of the eye. A specialist of vast experience stated that he had seen but one case in a soldier since the outbreak of the war and this was the result of a cataract operation. The author himself has seen one case in a soldier which supervened *after* prophylactic enucleation.—*Journal de Médecine et de Chirurgie Pratiques.*

A CASE OF ASPIRIN HABIT.

By DAVID I. MACHT, M.D.,

BALTIMORE, MD.

THE following case is deemed interesting enough from the pharmacological and therapeutic point of view and rare enough to warrant reporting.

Mr. D. M. S., 37 years old; white; married; occupation, teacher. He complained of pain in the right leg. There was nothing of note in the previous history and family history; no history of lues.

The symptoms date back to three years ago and began with pain in the right shin bone with gradual thickening of that bone. Patient complained of a constant pain of a gnawing or aching character experienced both by day and night, and consulted a large number of physicians without much satisfaction to himself. Careful investigation of the case led to the diagnosis of a chronic periostitis and osteitis of obscure origin. Repeated Wassermann tests were always negative; *x*-ray examinations and microscopic study of a piece of resected bone excluded neoplasm (sarcoma).

The patient was found to be pale and under-nourished, very neurotic; heart and lungs were normal; blood pressure rather low, 105/70; abdominal examination revealed nothing remarkable. The right shin bone (tibia) was found to be slightly thickened, not tender and not inflamed. There were no skin eruptions. The urine was negative for albumin and glucose.

Therapy.—The most interesting feature about the above case was the treatment employed by the patient for the relief of his pain. About two and a half years ago he found that a tablet of acetyl salicylic acid (aspirin), 5 grains, gave him distinct relief and he therefore continued to take the drug for the relief of his symptoms. It was found by him at the beginning that one or two 5 grain tablets were sufficient to keep him comfortable the whole day, but very soon habituation was noted and the patient had to increase the dose. For the past two years he has been taking from five to twelve tablets of aspirin daily; in other words, 25 to 60 grains of the drug have been consumed by the patient every day for nearly two years. The writer is not aware of any other instance on record in which a patient has taken such large quantities of acetyl salicylic acid over so long a period of time. It is remarkable that in spite of the enormous quantity of the drug consumed, very few toxic symptoms have been noted by the patient himself or found upon physical examination. The only features of a slightly abnormal character found were obstinate constipation, slight digestive disturbances, and a rather low blood pressure.

Medicolegal Notes.

Right to Recover for Services.—The Texas Court of Civil Appeals holds that a physician to recover for services must show compliance with the statute regulating the practice of medicine, and declaring unlawful practice without such compliance.—Paine v. Eckhardt (Tex.), 203 S. W. 459.

Using Mails to Defraud—Sale of Compound Wrongly Labeled "Acetyl Salicylic Acid."—Error was brought to the Circuit Court of Appeals, Sixth Circuit, from the federal district court for the eastern division of the Northern District of Ohio, on account of a conviction for using the mails to defraud, in violation of section 215 of the Criminal Code. Stating only so much of the alleged scheme as pertained to one of its several branches, it was this: Defendant was a physician, doing business also as a manufacturing chemist. The drug, acetyl salicylic acid, which had been manufactured in Germany, had become rare and high priced. The defendant made a compound from other comparatively cheap drugs (one of which was acetanilid), which compound he labeled and sold under the name "acetyl salicylic acid," and, although he made it in Cleveland, he caused the labels to say that it was manufactured by a fictitious firm in Germany. He did not sell this through the mails, nor, so far as appeared, in interstate commerce; but the genuine and common drugs which he used in his composition he procured by means of a written order therefor sent through the mails to manufacturing chemists in Philadelphia. Upon the sending of this letter rested the supposed violation of section 215.

He claimed in defense that acetyl salicylic acid was not compounded by any standard formula, and that his product was, in fact, acetyl salicylic acid and had all its therapeutic effects—or, at least, that he in good faith and reasonably so believed and had no intent to deceive. This defense was tried at length, was submitted to a jury under a charge to which there was no exception, and was found to be untrue.

The Circuit Court of Appeals held that the defendant's use of the mails fell within section 215 of the Criminal Code, denouncing the offense of using the mails in connection with a scheme to defraud. The trial court rightfully refused to charge that if the defendant honestly believed that his product was rightly called acetyl salicylic acid, then the fact that he intended to sell it under labels indicating that it was made by a fictitious firm in Germany would not constitute a violation of the act. It was not denied that drugs of this class had been commonly made in Germany, and that there was a common belief that the German origin was important as tending to insure the quality and therapeutic value of the drug. Under these conditions, the claim of German origin might well be the controlling consideration in bringing about a sale; and that the defendant believed it would be a material inducement was evident from its adoption by him. It is now well settled that whether the purchaser gets something "equally as good" and whether he gets an article actually worth the full price he paid are not controlling. If it is intended to bring about a sale by misrepresenting the quality or identity of the article in particulars which would be likely to have a persuasive effect upon the purchaser's mind, this would be a sufficient defrauding.

An instruction allowing the jury to consider the fact that the compound was not labeled as required by the federal Food and Drug Act, although, as the sales were intrastate, that act had no application, was held proper on the question of intent to defraud, and not erroneous as allowing the jury to consider another offense. This act was generally familiar to druggists and physicians the country over—the final customers whom the defendant intended to reach; they commonly understood that because of the general enforcement and observation of this act, any compound containing acetanilid would disclose that fact on the label, and they would naturally believe that if a compound offered for sale was not thus labeled, they could safely use it in cases where acetanilid would be dangerous. If the defendant knew of this regulation, and hence knew of the effect it certainly had upon the purchasing trade, he would know that his conduct in omitting any mention of acetanilid from the label would inevitably lead to the deception and the defrauding of the ultimate customers for his article.

The vital question to be determined by the jury was whether the defendant actually intended such fraud and deceit by putting out his article as acetyl salicylic acid of German manufacture; and the charge was in substance only an instruction that in determining whether his intent was fraudulent or honest, they could consider the fact, if they found it to be a fact, that in the very same transaction he was intending to deceive and defraud the same people in another particular. Viewed in this way, the charge was held not objectionable, and was well within the settled rule which permits even complete guilt of another offense to be shown where the question involved is the defendant's intent, and where the other act has a direct bearing on that intent. The judgment was affirmed.—Edwards v. United States, 249 Fed. 686.

Military Medicine.

THE AMERICAN MEDICAL AND SURGICAL HISTORY OF THE WAR.

THAT Division of the Surgeon General's Office which is charged with the "collection and preparation of materials for a Medical and Surgical History of American Participation in the European War," has a task closely related to although less of an adventure than that of medical officers who throng overseas to guard the health and mend the hurts of American Expeditionary Forces.

Under the conditions of a World War, well advanced at the date of our entry into it, with at least two great nations in rightful possession of first honors, we should be satisfied if our projected history sustains the prestige of the medical history of our own Civil War. From present appearances our part in the present conflict will not be long enough to reduce materially the disparity between us and our Allies.

On the other hand, we have immense advantage in comparison with the men who made the history of the Civil War. At the end of that struggle the surgeon-general's office was not owner, or custodian even, of hospital records. It is said that medical officers were not allowed to copy the records of their own most instructive cases. Such men as Weir Mitchell and Da Costa found themselves separated by military regulations from either possession or use of records made by their own hands; though one of the two found it possible to circumvent the regulations.

There is an excellent statistical volume in that history, but the materials for the statistical volume were but a small part of the material produced by the war. The forms of record for sick and wounded were changed twice in the course of the war; required reports were sometimes not rendered; of reports rendered some were rejected as defective; and in the end it was held that the materials utilized represented about nine-tenths of the information sought.

Of medical records of recruitment for the Civil War, not a line was at the surgeon-general's command. Two statistical volumes concerning recruitment were produced in the office of the Provost-Marshal General. They concerned the medical examination of 508,000 men, approximately half the examinations actually made. The remainder were lost or rejected. The Sanitary Commission published a fine volume on the anthropometric records of the Civil War, prepared by a distinguished actuary, Benjamin Apthorp Gould. Our forbears really turned a discouraging situation into a splendid opportunity, and their credit is secure for all time.

In accordance with Special Order A. G., No. 196, of August 23, 1917, a plan was drawn up that has been followed since that date. It includes the interim reports and protocols by medical officers of the U. S. Army on duty as observers in England and France, collected from the War College and the Council of National Defense, and a catalogue giving a brief abstract of their contents has been mimeographed and circulated.

Memoranda to medical officers in the field, requesting that they collect material for this history have been printed and circulated.

Every effort has been made to collect the individual histories of the administrative divisions in the Surgeon General's Office, of the camps and of the base hospitals in the United States, and most of this material is now on hand.

Steps have been taken to secure continuity in these histories by means of semi-annual historical reports (for administrative divisions) and by medical war diaries (for camps and base hospitals).

Through a circular issued by the Hospital Division the commanding officers of base hospitals have been authorized to direct preparation of subject indices of medical and surgical cases with the tacit understanding that these become available for the use of the historical division at the end of the war; and to send in, as manuscripts or as reprints (either for records or publication), accounts of epidemics, group diseases or unusual medical and surgical cases occurring in hospital, as part of this history. In this way much of the historical material will be actually assembled during the war, and the delays occasioned by the priority of pension claims will be to some extent obviated. In England this plan is actually in process of realization through the publications of the Medical Research Committee (London).

A tabular statement concerning the movement of the preventable diseases has been made by this board each week since September, 1917. These tables based on the weekly telegraphic reports made to the Division of Sanitation concern thirty-one separate cantonments, and will be a first installment of the history of mobilization in its first year (September, 1917-September, 1918) and should be available shortly.

Arrangements have been made to take care of the historical material relating to American participation in the Western front, already accumulated in France, and for the accumulation of similar material in Italy (Southern Front).

Friendly relations have been established with the military authorities controlling the medical history of the war in Great Britain, France, and England.

As at present constituted the Division of the Surgeon General's Office charged with the duty of collecting and preparing the material for a Medical and Surgical History of American Participation in the European War consists of Colonel Champe C. McCulloch, Jr., M. C., U. S. A., Director (on overseas duty); Lieut.-Col. Casey A. Wood, M. C., U. S. A., Acting Director; Lieut.-Col. Fielding H. Garrison, M. C., U. S. A., in charge of Redaction, and Lieut.-Col. John S. Fulton, M. C., U. S. A., in charge of Statistics.

An advisory council, consisting of Col. Victor C. Vaughan, M. C., U. S. A., Col. William H. Welch, M. C., U. S. A., and Col. William J. Mayo, M. C., U. S. A., has been appointed to assist this board in passing upon applications for commission or employment, expansion of the board and other matters under advisement.

The present war, even if soon concluded, will supply many times the amount of material for history and statistics. The Surgeon General's

office, it is now certain, will have the medical records of the draft and all subsequent medical records for the use of the Division of Medical History. Perhaps it is too much to hope but it is believed that there will be as little as 10 per cent. discount on this material by reason of inherent defect or failure of transmission. Considering the early organizations for purposes of history, the scale of modern military medicine, and the facilities which American ingenuity has devised for handling historical and statistical material, the outlook for a complete, interesting, and early publication of a medical history seems bright enough. But the Division of History will have to press every advantage, if it hopes to match quite the history of '61 to '65, to say nothing of the prospect of "classing" as well as possible in the company of our Allies.

Shock and Blood Pressure.—Moreau and Benhamon related before the Société de Chirurgie that they went from case to case of shock with blood-pressure instrument in hand in the interest of diagnosis, prognosis, and treatment (*La Presse Médicale*, September 26). Using the Pachon oscillometer they noted three measurements, viz., differential pressure, index of oscillometry, and the equality or inequality of oscillations for each figure of the manometer. The three measurements jointly enabled them to estimate the force of the myocardium. An analysis showed that whenever a major wound subject had a differential pressure below 2, an oscillometric index below 1, and unequal oscillations he should be regarded as shocked and thus treated, even if the diastolic pressure was below 6—in fact, all the sooner on that account. Every shocked person with a good differential pressure (2 to 5), with good oscillometric index (1½ to 3), and with equality of oscillations will probably recover spontaneously from the shock, even if his minima is below 6. These statements hold good for all but cranial injuries. As a matter of fact these subjects never develop shock, but die with cardiac collapse. The authors make four varieties of shock from the viewpoint of treatment: (1) All the measurements are good and the patient should be taken to the operating room where he merely receives warmth and physiological serum with adrenalin. (2) The differential pressure is zero and the patient should be transfused and given camphor intravenously. Operation should be deferred. (3) The minima falls steadily and rapidly. In this class, like the preceding, hemorrhage is a marked component. These subjects should be rushed to the operaitng room, transfused and given massive doses of serum intravenously. (4) The differential pressure progressively diminishes, indicating infection or intoxication. These subjects should be rushed to the operating room where operative intervention can be carried out according to precise indications.

Septicemia During the Evolution of War Wounds.—Legrain has recently published an inaugural thesis on the septicemic component of war wounds irrespective of their severity. From an abstract in *La Presse Médicale* for September 19 we learn that the author made a study of thirty-two recently wounded soldiers and found evidence of septicemia in thirteen, or 40 per cent. No wound so slight that may not be thus complicated, but we usually expect to see them more frequently in osseous wounds. Mild and ephemeral sepsis is usually seen in slight wounds and is known only from the temperature rise. This may be left out of consideration. Acute severe sepsis represents a defence reaction on the part of the economy which lasts about ten days. The usual symptoms are hyperthermia, chills, sweats, rapid pulse, etc. In certain cases sepsis develops on a basis of shock due to traumatism and loss of blood. In such cases the sepsis pursues a fulminant course and the temperature may not ascend. A subacute form is seen which persists over a long interval and is characterized by recurrent fever. It is apt to be associated with pyemia and may also kill by exhaustion. There is a late septicemia due apparently to a period of latency. Of the author's 13 cases 5 ended fatally. All followed wounds of the long bones. The evidences of sepsis are locally the arrest of the healing process and the drying of the wound. Hence reappearance of pus in the wound or even appearance of erysipelas is an encouraging sign. Evidences of sepsis may be absent in certain cases in which suppuration goes ahead undisturbed and fever does not develop. The principal germs found were the streptococcus, pneumobacillus of Friedlander, and staphylococcus, in the order named. The bacillus, however, is not pathogenic to the extent of causing fatalities. The infection due to it was benign in all three cases and the same was true of a tetragenus case. The streptococcus is hemolytic as shown by the presence of hemorrhagic cases. The staphylococcus, despite its lower frequency, killed two of the five patients. The author brings out nothing new under treatment. If a case is not fulminant, nutrition, establishment of turpentine abscess, and serotherapy should be the mainstays. In the acute form amputation holds out the only hope by eliminating the focus of infection.

Hemeralopia in Soldiers.—This subject is shown by Danis, in the *Archives Médicales Belges* for July, to be a very ancient one and a record of it is found in the thirteenth century in connection with the Crusades, when members of the expeditionary force of Jean de Brienne suffered from night blindness while in Egypt, and at the capitulation of Damietta in 1221. The historians next find the affection mentioned in 1798 and curiously enough again in Egypt in Napoleon's army. It was also seen at about the same period at the siege of Malta. The besieged were the ones who suffered. The next mention appears to be in Russia in 1812, the author supplying no details. The affection was noted in the French expedition to Algiers in 1838 and again in the Crimean war in 1854-5. During the Russo-Japanese war it was studied in Manchuria and before the present world conflict it was studied by a French ophthalmologist in the Algerian colonial troops. In most of the garrisons in Europe, even in times of peace, cases occur and this is more marked in Eastern than in Western Europe. In the non-military population, the same disability has been encountered in unfavorable economic and hygienic sur-

roundings. Thus it has been known to prevail among the Fellahs of Egypt, the negroes on Brazilian plantations, sailors on long cruises, tunnel workers, and prisoners.

The Tuberculosis War Problem in Canada.—At the Fourteenth Annual Meeting of the National Tuberculosis Association, held in Boston June 6, 1918, Lieut.-Col. Jabez H. Elliott, C.A.M.C., gave an address on the manner in which Canada is meeting this problem. The address was published in the *American Review of Tuberculosis* for September, 1918. Among the various means adopted and carried out in Canada is the vocational training of consumptives. Elliott says that when the patient's disease is under arrest he is free to go on with reeducation if it be necessary for him to find a new occupation. In small sanatoriums only a few lines of reeducation can be properly developed. Stenography and typewriting are examples; cabinet making is another. The larger the sanatorium the greater is the number of trades and callings for which provision can be made. With the disease well under arrest, especially if the sputum is free from bacilli, the man may be allowed to begin his vocational work in one of the larger convalescent hospitals, which are completely equipped with workshops and schools. The experience of Elliott and his colleagues leads him to say that no military sanatorium is complete unless workshops and schools are provided. The post of vocational officer is an important one, second only to that of the medical officer with whom he must be in conference daily; for he must not only study the men from the point of view of the trade test and trade efficiency expert, but be a wise counsellor as well, and at all times be guided in the allotment of work by the limits fixed by the medical officer, which must of necessity vary with the patient's progress and be restricted by intercurrent infection or complications. The occupational therapy developed in the Canadian sanatoriums may be divided into (1) ward occupation, and (2) occupational therapy proper. The first is carried out in bed or on the reclining chair, and few patients are too ill to be interested in or benefited by this work. The second division is carried out in classrooms and workshop and comprises school studies, languages, civil service study, stenography and typewriting, and telegraphy, while light handicrafts are carried on in the workshops. The value of vocational work in the sanatorium treatment of the tuberculous soldier is well illustrated by the experience at Ste. Agathe. Before vocational classes were established 33 per cent. of the patients refused treatment and 15 per cent. were discharged as delinquents or incorrigibles. With vocational work well developed none has refused treatment; and only 0.5 per cent. have been discharged as incorrigibles, while 7 per cent. have asked to be retained beyond the time when ready for discharge, that they might have a further course of study or training.

Tribute to Ex-Surgeon General Gorgas.—Major General William C. Gorgas, who has just returned from an inspection trip in France, has received a letter from Secretary Baker which has been made a part of his military record, expressing the appreciation of the nation of General Gorgas' disinguished services during his long career as a medical officer of the army.

Training Nurses' Aids for Overseas Service.—The New York County Chapter of the American Red Cross announces that it has started classes for the training of nurses' aids for service in the war hospitals of France. The classes are being held at the Red Cross Teaching Center, 453 Madison Avenue, New York City. These classes were formed as a result of a call from Surgeon General Ireland, who has asked for 1,500 nurses' aids for overseas service. Application for overseas service as aids should be made at the headquarters of the New York County Chapter of the American Red Cross, 389 Fifth Avenue.

Yale Hospital Unit.—A correspondence recently made public by Yale University describes the work of the Yale Mobile Hospital Unit, which was the pioneer unit of its kind in the American Army, and rendered important service in the St. Mihiel offensive. Although 144 operations in twenty-four hours was considered the maximum, 170 were performed by the unit in the first twenty-four hours of the drive. The unit is known as Mobile Hospital 39 and has been enlarged so that it now includes 250 persons.

Mark Twain's Home a Rest Cure.—The Mark Twain estate, Stormfield, at Redding, Conn., has been given by his daughter, Madame Ossip Gabrilowitsch, for the use of convalescent soldiers and sailors of the artistic professions.

Influenza in Army Camps.—From the beginning of the epidemic to October 24 there were in the army camps a total of 296,275 cases of influenza and 48,328 cases of pneumonia, with 16,174 deaths. Camps Dix, New Jersey, and Grant, Illinois, where the epidemic has been particularly severe, have not reported any new cases, and only a few new cases have been reported from Camp Devens, Mass. Camp Meigs, Georgia, reports no new cases. There has been a marked decrease in the number of new cases of pneumonia and in the number of deaths from that disease.

Deaths in the Service.—Lieutenant Marcus Calvin Houser, M. C., U. S. Army, of Charlotte, N. C., a graduate of the North Carolina Medical College, died of pneumonia following influenza, at Camp Jackson, on October 8, aged 31 years.

Lieutenant Niel Franklin Twigg, M. C., U. S. Army, a graduate of Johns Hopkins University, in 1916, died of pneumonia at Fort Oglethorpe, Ga., on October 10, aged 24 years. In 1916 he went to England, where he served for eighteen months in a base hospital.

Lieutenant Joseph Devine Rosenthal, M. C., U. S. Army, of Rockaway Park, L. I., died of pneumonia, in the base hospital at Markleton, Pa., on October 22, aged 27 years. He was a graduate of the New York Homeopathic Medical College, in 1915.

Dr. Vivian Slaughter, a recent graduate of the University of Virginia, met death in action on the battle front. He joined the Medical Corps of the British Army in 1914 and had since been in active service. The details of how he came to his death have not been received.

MEDICAL RECORD.

New York, November 2, 1918.

THE RAPIDITY OF PROPAGATION OF THE VENOUS PULSE WAVE IN MAN.

FOR some time past the rapidity with which the pulsatile waves pass through the arterial tree has been studied and determined with the variations that it may offer under the influence of various factors. This, however, is not the case with the venous pulse wave, either because one attributes to it too readily a rapidity of translation equal to that of the arterial pulse or because the elements of the estimate are too difficult to bring together. The literature, however, contains some researches in this direction. Morrow found that in dogs the venous wave had a retrograde translation of from one to three millimeters per second, while Frédéricq speaks of a speed of about two millimeters per second.

Clinically, in spite of the development of phlebographic studies very little has been done on the question under consideration, but quite recently Betchov (Contes rendus de la Soc. de physique et d'hist. naturelle de Genève, April, 1918) has studied the arterial and venous pulse simultaneously in two children, one with a pleural collection, the other with an endocarditis, which resulted in a dilatation of the right heart so that it reached under the sternal tip at which point the beats could be registered. Both tracings are about alike and show that the principal wave of the cardiogram corresponds to the auricular systole, the ventricular beats are weak, indicating an asystolia of the right ventricle. Therefore, this offered the means of noting the beginning of the auricular systole, while the chronographic comparison with the first wave of the jugular pulse permitted the calculation of the speed of translation of this presystolic wave of the venous pulse.

The delay was found to be 0.08 of a second in the first case; the distance between the epigastrium and jugular vein being 20 centimeters made an estimate of 16 centimeters as the maximum distance of the outlet of the superior vena cava from the point of application of the bulb of the phlebogram. It was found that the venous wave was propagated excentrically at the rate of two meters per second. In Betchov's second patient the delay of the presystolic wave was 0.07 of a second, which gave an undulatory rapidity about identical with that of the first case if the smaller size of the patient's thorax be taken into consideration.

From this it will be seen that the data obtained in man are in accord with experimental results in animals. But the venous pulse is composed of several waves and the question arises as to how they act from the viewpoint of their rapidity of transport. Do they offer differences of speed which might speak in favor of a different manner of production in the case of certain waves which might cause a revolution of the phlebogram? Betchov, no more than Morrow, found a really perceptible difference in the duration of translation of the different waves, and their manner of propagation appeared to be alike in all.

Now, as to the explanation of the great difference between the rapidity of the arterial waves (9 to 10 meters per second) and that of the venous waves at two meters per second, one might be tempted to suggest that one travels in the direction of the current, the other in an inverse direction, but this factor is powerless to cause such a great difference in the speed. The blood pressure need not enter into consideration because Morrow's work shows that he was unable to establish any relationship between the rapidity of transmission and the blood pressure in the veins. The determining factor must evidently be looked for in the conditions of extensibility and elasticity of the vessel walls. The researches of both Rocque and Grünmach show that the pressure of the fluid contents does not increase the rapidity of translation of the waves only in so far as it wears out the extensibility and increases the elasticity of the containing tube.

Applying these data to the physiology of the circulation, the conclusion seems logical that the low rapidity of translation of the venous pulse waves is due to the great extensibility of the venous walls. Their elasticity absorbs and breaks the retrograde waves coming from the heart and prevents a rapid translation, such as is realized in the arterial system.

HYDATIDIFORM MOLE AND CYSTIC DEGENERATION OF THE OVARIES.

CYSTIC degeneration of the ovaries very frequently is found in conjunction with hydatidiform mole. The ovarian process is bilateral, and although the size of the two glands may be unequal they are both of the same histological characters as microcystic ovaries arising from quite another cause, such for example as infection or gestation. In other words, there is an exaggeration of the number of follicular atresias and a hyperproduction of the luteinic cells of the theca, the organ of internal secretion of the ovary. Between a hydatidiform mole and a cystic degeneration of the ovaries there seems to be a relation of cause and effect. The primary cause appears to reside in the activity of the epithelial lining of the degenerated villosities provoking a reaction in the glandular functions.

The cystic ovary of the mole is not permanently lost to reproduction, because after the mole has been expelled the ovarian process usually undergoes a complete regression and later on may give issue to a normal ovum so that a subsequent pregnancy with a viable fetus is possible.

There is no special symptomatology pertaining to a mole with cystic ovarian degeneration, yet when a woman offers the usual signs of pregnancy but in an exaggerated form with uncontrollable vomiting, albuminuria, increased pulse rate, and early cachexia, the possibility of a hydatidiform mole must be considered. When there are serous discharges tinged with blood or even true hemorrhages which may occur very early in the process, an increased pulse rate, and a uterus inordinately enlarged, the probability approaches certainty and the certainty will be complete when the vesicles of the mole are expelled, these usually being followed by the mole itself.

All these symptoms lead to the diagnosis of a mole but not of cystic degeneration of the ovaries. The apparition of this process varies and it is not at all improbable that it may be present from the beginning of the molar pregnancy, but no case in support of this supposition has been recorded. When it is contemporary with the pregnancy and evolutes with it no clinical manifestation of its presence is evident. The symptoms of compression, such as edema, dysphoria, constipation, etc., arise only when, besides a very large uterus, the cysts in the ovaries are extremely voluminous. The pains that the patient occasionally complains of in the iliac fossæ are not of a nature to be attributed to cystic ovaries and there remain only the data to be obtained by digital examination, which are of real value. By carefully outlining the uterus, one may feel one or two rounded masses beside this organ, of a softer consistency than the uterine mass. In size and position they vary, but if they possess a sufficiently long pedicle they are forced upward by the rapidly enlarging uterus and may be found at the inlet of the true pelvis or even in the hypochondrium.

Usually these cystic ovaries are to be found on the sides of the uterus, with which they not infrequently form one body and very often one of the ovaries will be found deeply lodged in Douglas's pouch. It may happen that during the evolution of a molar pregnancy the diagnosis of cystic degeneration of the ovaries cannot be made on account of their small size or because they are hidden by the uterus, and in some cases it has only been at a subsequent operation determined by ovarian symptoms that the cystic degeneration has been demonstrated to exist.

After the mole has been expelled a regression of the cystic process usually takes place, while, on the contrary, for reasons that probably are to be found in the retention of débris or molar elements in the uterus, the ovarian cysts rapidly attain a considerable size and give rise to lumboabdominal pain, sometimes of a violent character, which may be attributed to the compression exercised by the cysts or to torsion of the pedicle. Blood-stained serous discharges or even hemorrhages are symptomatic of cystic degeneration of the ovaries and find their explanation in the persistency of the neoplastic process in the uterine cavity and not, as Pouget would have it, in relating them to the intensity of the internal ovarian secretion which would give to the uterus a vasodilating and hemorrhagenic action.

Xiphoid Crepitation.

In 1873, Galvagni described for the first time a phenomenon termed by him xiphoid crepitation, but not until 1916 did a monograph appear on the subject, by Campani. In the interim, Bernabei sought to explain the nature of this induced symptom as follows: Whenever there is emaciation, with absorption of subcutaneous fat, a crepitus is obtainable, due to the friction of the loosened skin on the subjacent tissues. From this angle there would be nothing characteristic about the symptom in its occurrence in a given locality. Galvagni had imagined the formation of gas bubbles as if a species of subcutaneous emphysema was present and he believed that the seat of these bullæ was subperitoneal rather than subcutaneous. Campani held the bubbles to be subcutaneous in site, but connected in some way with the peritoneal lymph circulation. In *Il Policlinico* of September 1, Bergoli, assistant to Professor Campani, reports 12 cases of this symptom as noted in typhoid fever subjects, all of whom were soldiers. The first case narrated was one of moderately severe typhoid in the stage of convalescence. It was found that the liver was enlarging, and in palpating its edge the phenomenon of xiphoid crepitus, with fine bullæ, was obtained. This could be elicited for 20 days, after which it could no longer be felt. In this case, late meteorism had supervened along with the enlargement of the liver. The behavior of the other cases from this viewpoint showed a decided adherence to type and the author interprets the phenomenon as associated in some way with peritoneal irritation. The liver showed a variable degree of enlargement. The crepitus could not be elicited in two cases in which peritoneal irritation and enlarged liver were present, but the association was positive in a large series of cases of this coincidence. In every case in which the symptom was present there was much meteorism in the upper portion of the abdominal cavity, and as far as the author has gone the crepitus is a phenomenon of the acute abdomen including typhoid fever. Experiments appear to show that the subcutaneous connective tissue is the seat of the crepitus, and the only hypothesis which fits the condition is that of the existence of a disturbance of the lymphatic circulation.

The Pathology of Courage.

The idea of courage implies that fear has been overcome, not that it did not exist. We can hardly conceive of courage apart from fear—such a state of mind would not be courage, but something else. Claims have been made that fear is something essentially pathological because of the character of its

manifestations. But fear is also normal, because implying the act of self-conservation. There are, of course, normal fear and morbid fear, and so one may say that some courage is natural and some pathological. The latter, according to Voivenel, in *Le Progrès Médical* for August 3, is a sort of affective drunkenness. In normal courage one has presence of mind, is master of himself. Not so in morbid courage. In the former we may speak of heroism and heroes, but in pathological courage such terms are out of place. From this viewpoint, Coriolanus, as depicted by Shakespeare, showed morbid courage, for when he became angry in battle he forgot the name of death. Voivenel seeks to explain some morbid courage by an enhanced sentiment of tribal altruism, such as is seen among primitive peoples. In the absence of an object, as when one's people have been sacrificed, the sentiment persists as *felo de se*. According to this view, the Romans, who fell upon their swords after the cause was lost, were irresponsible, and did not act in cold blood. There are other components in morbid courage, as when it is the result of ignorance of danger; this is seen in children and in inexperienced people in general. There are also lovers of adventure who cannot enjoy themselves unless they are in some peril. Morbid courage is seen at times in the unbalanced, and of course in the downright maniac. It has been claimed by criminologists that a boy who does not fear to attack a grown man on even terms is always a degenerate. Desperadoes work themselves up gradually to a state of fury before attempting to "clean out," single-handed, some resort for their kind, and the Malay who runs amuck may behave in a similar manner.

The Health of the German Woman.

A WRITER in *La Presse Médicale* for September 5 discusses this subject on a basis of data obtained from miscellaneous sources. What is true of the German woman applies even more strongly to the women of some of the overrun border countries—Poland for example. The first topic for discussion is emaciation from underfeeding. It was shown of certain women of Warsaw that they received daily but 1400 to 1800 calories. As a result the melting away of the fat of the lesser pelvis and abdominal cavity caused enteroptosis, chiefly in the form of nephroptosis. Other ptoses as those of the liver and stomach were sufficiently evident and good opportunities for palpation of viscera were plentiful. The broad ligaments relax and the perineum follows; the gynecologists perform prolapse operations nearly fourfold as frequently as before the war. War amenorrhea or rather amenorrhea in general is sevenfold more common; or, in other words, 7 out of every 100 women who should menstruate are unable to do so. Many believe themselves pregnant and some even have milk in the breasts. These cases will doubtless recover as soon as life becomes normal. The proportion of male births certainly increases, being now 116 to 100 girls, with a maximum of 122 to 100 in some statistics. Whether the predominance is a teleological phenomenon to offset the male deaths or a mere result of underfeeding must be left to the readers' own judgment.

News of the Week.

Influenza Epidemic on the Wane.—Reports received by the United States Public Health Service from 44 States indicate a subsidence of the epidemic, though the situation is still serious in some localities, particularly in the Northwest. In the states bordering on the Mississippi River there has been a decline in the number of new cases. Improvement is also seen in the South and the East, though the disease is still active in the large cities. In New York City, from the beginning of the epidemic on September 18 to October 26, there have been reported 93,297 cases of influenza, with 6,325 deaths, and 12,369 cases of pneumonia with 6,032 deaths. A comparison of the records of New York City with those of Boston and Philadelphia indicate that the mortality in New York has been much lower than in those cities. In Boston during the four weeks before the appearance of the epidemic the annual death rate was 13 per 1,000 population. In the first week of the epidemic the rate increased to 15 per 1,000; in the second week it was 33; the third week, 67; the fourth week, 100; the fifth week, 101, and in the sixth week dropped sharply to 52 per 1,000. In Greater New York the figures before the epidemic showed an annual death rate of 10 per 1,000, and in the successive weeks of the epidemic the rates per 1,000 increased as follows: first week, 12; second week, 16; third week, 29; fourth week, 50. In Philadelphia the normal rate before the epidemic was 12 in every 1,000. In the weeks of the epidemic this advanced first to 18 per 1,000, then to 36; in the third week to 97, and in the fourth week to 158 in every 1,000. Few new cases are being reported in Boston and the discharges from New York hospitals are greatly exceeding the new admissions. The figures of the New York State Health Department show that the total number of deaths for the State outside of the City of New York for the first 22 days of October was 4,543, of which 3,313 were attributed to influenza and 1,230 to pneumonia. In San Francisco a city ordinance has been passed compelling the wearing of gauze masks by every person. The masks may be removed only in homes and during meal times.

Influenza in Other Countries.—A serious epidemic of influenza is ravaging Copenhagen. No family is spared, the hospitals are overcrowded with ill, and many are dying of pneumonia. In order to stop the infection the Government has closed all places of amusement and the churches are being used as hospitals. The mortality is extraordinarily high. Medical reports show that the epidemic of influenza is striking harder in Great Britain, France, and Italy, but especially in England. Most of the deaths in England occur among those between 25 and 35 years of age. In South America the influenza epidemic is still on the increase in many localities. The disease prevails to such an extent in Brazil that the Government has issued a decree suspending official business until the epidemic is over. In Argentina it has seriously hampered business and other activities. The Government has ordered all schools closed until further notice. Eighty thousand cases of

influenza are reported in Colombia. There have not thus far been many cases on the Isthmus owing to the strict quarantine that is being maintained. The epidemic has spread to virtually all parts of Mexico and is causing many deaths in some localities. Trains on the national railroads are being disinfected by the Government.

New York State Commission to Study Influenza.—Governor Whitman has appointed a Commission to study and report on the cause, prevention, and treatment of influenza. Those asked to serve are representatives of the Army, Navy, and Public Health Service; Dr. Rufus I. Cole of the Rockefeller Institute of Medical Research; Dr. Walter B. James, president of the New York Academy of Medicine of New York City; Dr. Hermann M. Biggs, New York State Commissioner of Health, and Dr. William H. Park, director of the research laboratories of the New York City Department of Health.

New Jersey Health Department Arraigns Mayors.—The New Jersey State Board of Health recently adopted a resolution calling upon the police authorities of Newark and Jersey City to enforce an order against public gatherings during the epidemic of influenza. The mayors of these two cities lifted this ban without consulting the State Board of Health, and are now to be summoned before this body—if authority for such action can be found—to explain why they interfered with a ruling of the State Board of Health. Mayor Gillen of Newark has counter-attacked in a letter to Governor Edge demanding the resignation of the State Director of Health if the Governor finds upon investigation that the state-wide quarantine was ordered by Dr. Price without sufficient authority.

Limit Surgical Operations During the Epidemic.—Dr. Edward P. Davis, President of the Volunteer Medical Service Corps, has called upon the medical profession of the nation to perform no surgical operations except those absolutely necessary to save life during the influenza epidemic. He further advises that no medicine or treatment be prescribed by the profession which might depress the vital functions of the patient.

Red Cross Aids Tuberculosis Fight.—The Red Cross has appropriated $2,500,000 to insure the continuance of the anti-tuberculosis campaign in this country which has for some years past been dependent on the sale of Red Cross seals at Christmas time. The seals will not be sold as in former years. The State Charities' Aid Association will handle New York State's share of the appropriation.

New York Infirmary Seeks Funds.—The New York Infirmary for Women and Children began a campaign last week to raise $200,000, which is necessary if the institution is to continue its work. The infirmary was founded sixty-five years ago and has never before been compelled to appeal to the general public for support. During the past year 700 mothers and new-born babes have been cared for, 643 operations performed, and more than 53,000 patients treated in the institution and its clinics.

San Salvador Quarantines Against Yellow Fever.—Because of the prevalence of yellow fever in Guatemala the Salvadorian Government has ordered that the frontier between Guatemala and Salvador be closed.

Narcotic Drug Law Modified.—In order to facilitate the fight against the influenza epidemic, the Internal Revenue Collector in the Third New York District announces the modification of the law prohibiting the refilling of narcotic drug prescriptions. The modification reads as follows: "Prescriptions calling for morphine, codeine, or heroin, which are written by registered practitioners for patients suffering from influenza and any pulmonary or bronchial affections may, until further notice, be refilled, provided that at the time of issuance by physicians instructions are noted in the body of such prescriptions. 'Repeat if necessary,' and the druggist filling and refilling the same shall note thereon each and every date upon which such prescription is refilled."

Dr. George Chaffee of Brooklyn, N. Y., who was formerly on the surgical staff of the Polyclinic Hospital, has located in the city of Binghamton, N. Y., where he has opened an office at 100 Hawley Street.

The National Committee for the Prevention of Blindness will hold its annual meeting in the New York Academy of Medicine, New York City, on November 26, 1918, at 8.30 P.M. The chief speaker of the occasion will be Lieutenant Colonel James Bordley, whose subject will be "The Government and Red Cross Work for Blinded Soldiers."

The Southern Medical Association has abandoned its annual meeting which was to have been held at Baltimore on November 11-14 on account of the epidemic of influenza.

The German Birth Rate.—An official report prepared by the Intelligence Department of the Local Government Board in Germany which has found its way to America, shows that the total number of births in Germany, in 1916, was about 40 per cent. less than in 1913. The infant death rate during the war has at times risen to 200 and 300 per 1,000 births. In some parts of Germany infant welfare work has met with marked success and the high mortality rate has been considerably reduced. War conditions in Germany are said to have produced a new type of baby which the German doctors call "war infants." These infants are said to be not actually ill, but small, backward in growth, delicate, thin, with wrinkled skins, suggestive of age rather than infancy. It is reported that 23 per cent of the children brought to the infant welfare centers in Charlottenburg were suffering from rickets in some degree and that 43 per cent. of those brought to the welfare center at Treves were suffering from the same disease.

Obituary Notes.—Dr. DAVID WEBSTER MEYER, a graduate of the Long Island College Hospital, in 1904, died of pneumonia at his home in Brooklyn, on October 24, aged 47 years.

Dr. JOHN E. KER of Kingston, Jamaica, who was making a tour of the United States to study sanitation, died of meningitis in the Post-Graduate Hospital, New York, on October 24. Dr. Ker was a graduate of Oxford University, England.

Dr. STANLEY OWEN SABEL, a graduate of the

College of Physicians and Surgeons, New York, in 1898, died suddenly at his home in New York City, on October 20, aged 42 years.

Dr. M. S. Black, a graduate of the College of Physicians and Surgeons, New York, died of pneumonia in St. Vincent's Hospital, Williamstown, Mass., on October 4, aged 40 years.

Dr. Gerard H. Lebret, a member of the staff of the Overbrook Hospital, died of pneumonia at his home in Montclair, N. J., on October 17. He was a graduate of the University of Maryland and recently commissioned a Lieutenant in the Medical Corps of the Army.

Dr. Robert S. Topping, a graduate of the New York University and Bellevue Hospital Medical College, in 1913, died of pneumonia following influenze at the Presbyterian Hospital, Newark, N. J., on October 11.

Dr. Ernest Fly of Johns Hopkins Hospital, Baltimore, died of influenza, in Baltimore, on October 13. Dr. Fly was just recently appointed head of the Rockefeller Foundation Hospital at Pekin, China.

Dr. Abraham Korn of New York died of pneumonia at his home on October 13, aged 55 years. He was a graduate of the College of Physicians and Surgeons of Columbia University, in 1885.

Dr. Bernard William Junge, a graduate of the Buffalo Medical College, in 1900, died after a brief illness at his home in New York, aged 49 years.

Dr. Albert T. Chambers of Baltimore died from influenza at his home, on October 14, aged 43 years. He was a graduate of the University of Maryland, in 1898, for several years assistant professor at the University of Maryland, and later professor of operative and clinical surgery at the Maryland Medical College.

Dr. J. Marye Lewis of Manassas, Va., a graduate of the University of Virginia School of Medicine, in 1905, died of pneumonia, on October 14, aged 37 years.

Dr. Lawrence J. Simonton of Cumberland, Md., died at Centerville, Md., on October 12, aged 38 years. He was a graduate of George Washington University Medical School, in 1909.

Dr. Walter E. Gregory, a graduate of the University of Buffalo Medical Department, in 1889, and for many years on the medical staff of the Jackson Health Resort, at Dansville, N. Y., died of pneumonia in that city, on October 26, aged 61 years.

Dr. Emanuel Joseph Leavitt, a graduate of the College of Physicians and Surgeons, New York, in 1904, and radiologist to the Wyckoff Heights Hospital, died of pneumonia at his home in Brooklyn, on October 24, aged 47 years.

Dr. Leo Smith Petersen of New York, a graduate of the College of Physicians and Surgeons, New York, in 1911, died of pneumonia in the Lenox Hill Hospital, on October 23, aged 31 years. He was captain of the First Field Ambulance on the Mexican border, a member of the staff of the Lenox Hill and the Skin and Cancer Hospitals, and president of the medical fraternity of Chi Zeta Chi.

Dr. William A. Keeley, a graduate of the New York University Medical School, in 1888, died of pneumonia at his home in Brooklyn, on October 20, aged 51 years.

Obituary.

ROBERT COLEMAN KEMP, M.D.

NEW YORK.

Dr. Robert Coleman Kemp, whose death from pneumonia occurred on October 23, was born in 1865 and was graduated from the College of Physicians and Surgeons, Columbia University, in 1889. After serving an interneship at Roosevelt Hospital he entered on practice in this city, turning his attention early to diseases of the digestive tract. He was a professor of gastrointestinal diseases at Fordham University, visiting physician in the same branch of medicine at the Fordham University clinic, and consulting gastroenterologist to the Manhattan State Hospital. He was a member of the Medical Societies of the County and State of New York, of the American Medical Association, the American Urological Association, the American Therapeutic Society, the Gastroenterological Association, and the New York Academy of Medicine. Dr. Kemp was the author of a well known textbook on diseases of the stomach, intestines, and pancreas, of which a third edition appeared a couple of years ago.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

MEDICAL MEN FOR THE HOUSE OF COMMONS—DEATH OF DR. CLARA HIND—THE MINISTRY OF HEALTH AND LONDON PANEL PRACTICE—WORK OF NATIONAL SERVICE MEDICAL BOARDS DURING 1918.

London, October 3, 1918.

A largely attended meeting of members of the medical profession was held on Tuesday, October 1, in the Steinway Hall—before the war the fashionable London center for musical reunions—for the purpose of taking steps to secure more adequate representation of the medical profession in Parliament. The meeting was presided over by Sir Henry Morris, an ex-president of the Royal College of Surgeons of England, who was supported by, among others, Dr. Christopher Addison, Minister of Reconstruction, Sir William Watson Cheyne, member of Parliament for the University of Edinburgh, and Dr. Chapple, member of Parliament for Stirlingshire. Sir Henry Morris opened the proceedings with the obvious statement that after the war the medical profession would share in the same profound social changes that would characterize every other calling in the country, while he pointed out that the grant of limited suffrage to women had increased the electorate by six millions. In the general work of international, domestic, and social reconstruction and regeneration medical men would certainly play a prominent part, and no one could doubt that an adequate representation in Parliament would enormously increase their proper scientific influence. He laid stress on the necessity that all steps taken by doctors to obtain better representation in Parliament should be met by common effort and not by particular unions or associations, a view that was highly approved by an audience that is a little weary of group movements among its members. The new part of Sir

Henry Morris' speech was his conclusion that some form of direct representation ought to be secured in Parliament for medical men, owing to their feeble chances of securing election upon general grounds. Dr. Christopher Addison then moved a resolution that medical men ought to be more adequately represented in Imperial Parliament, and proceeded to give a sketch of the life of the private member, for, as he premised, medical men in Parliament can only expect to be private members for individual constituencies, though united by their common profession when subjects of public health are on the *tapis*. Dr. Addison supported Sir Henry Morris in the position that profound social changes having distinct medical bearings must be expected in the immediate future, and roused the curiosity of his hearers, who thought that he was going to give to a purely medical audience some forecast of the provisions which will be included in the coming bill for the creation of a ministry of health. Dr. Addison, however, while suggesting that the public ought to place greater confidence in doctors, withheld his confidence from his professional brethren, whereby his presence at the meeting greatly lost its significance. Dr. Arthur Latham seconded Dr. Addison's resolution, and his clear and able speech secured its unanimous adoption. But from this point the proceedings did not go quite so harmoniously. A second resolution was brought forward for the constitution of a provisional committee whose duty it should be to advance the claims of medical men who desired to become candidates for parliamentary honors, and the meeting grew restive under the idea that the committee, if selected, intended to support certain medical men already before their constituencies while neglecting the claims of other medical men. Verbal alterations in the resolution at length secured its adoption, but in a form which may lead to considerable inconvenience. For the resolution appears to bind the committee to support medical men in their constituencies regardless of the fact that there might be, as there certainly will be in the case of one of the best-known universities, two medical men contesting the seat from different political points of view. When the terms of reference of the committee had been settled the committee was elected, its composition being (1) representatives of a large group of public medical bodies, (2) the editors of the *British Medical Journal* and the *Lancet*, and (3) a group of unofficial members selected by the suffrages of the meeting. The probability is that the committee will not find much to do at the general election which is believed to be imminent, inasmuch as the official candidates of the recognized parties will most likely obtain the votes of the constituencies under the old-fashioned party system, and all such official candidates have already been chosen, and do not include many medical men. No medical man can expect to get into Parliament on the mere claim that he is a doctor. His position should be that he is a member of Parliament, qualified generally by his admission to a learned profession to show judgment in general affairs, while qualified particularly to assist the House in coming to a conclusion in particular and important provinces of sociology. As long as the system of party government prevails in this country the medical man must obtain his votes upon the general ground, and here he requires the assistance of party organization. Having got into Parliament upon the general ground, his particular gifts can be used by the House of Commons. The probability is that in the near future many constituencies will recognize the fitness of medical men for Parliament, but no such recognition exists at the present moment, while the appalling waste of infant life, the general problems of sanitation and rehousing, and the special problems of the care of the wounded and disabled of the war will be among the most pressing subjects for parliamentary debate. There are at the present moment in the House of Commons, out of 670 members, 300 following the various commercial callings, or business men, 170 lawyers (which many people think 165 too many), and 10 doctors, only two or three of whom are in active practice. It is obvious that a medical voice of such tiny volume is practically unheard.

The death has occurred of Clara Hind, one of the pioneers among English medical women. She began as a nurse. She specialized in obstetric nursing, and became matron of a maternity hospital. While so employed she entered as a medical student at the London School of Medicine for Women, and qualified some twenty years ago, doing her clinical work at the Royal Free Hospital. From that time she devoted herself to the open-air treatment of phthisis, and at the time of her death had managed for fifteen years the Ockley Sanatorium.

This much has transpired from the recent speeches of public men—the ministry of health is to be instituted in the coming session of Parliament if the pressure of public affairs admits, and it is to be, in the first instance, a collation and coordination of existing activities and not the creation of any state or regimented medical service. The London Panel Committee, speaking for medical men who minister, or who in times before the war were ministering to the medical needs of some 3,000,000 persons, have recently passed the following resolution, etc., while heartily approving of the scheme of the British Medical Association for the constitution of the ministry of health:

"We nevertheless think that the method proposed for the appointment of the medical members of the Advisory Council is not conducive to 'keeping the minister in living touch with those bodies and classes of persons on whose cooperation the success of the new ministry would depend,' and we therefore recommend that the following resolutions be sent to the Minister of Reconstruction, the Local Government Board, the Insurance Commissioners, the Board of Education, and the Ministry of Pensions: (a) That this committee are of opinion that (1) the members representative of the medical profession upon the Advisory Council should consist of not less than one-third of the total membership, and (2) that a majority of the representative members of the profession should be nominated by the statutory medical committees. (b) That this committee are strongly of opinion that the medical functions of the Board of Education and of the Ministry of Pensions should be incorporated in the ministry of health.

These recommendations of the London Panel Committee are full of wisdom. That the ministry of health, whatever its shape and scope, will be

guided by an advisory council on which medical men will have seats is certain; but unless the medical voice is a strong one it may be ineffective, and a powerless medical minority be credited in the public eye with having acquiesced, from a medical point of view, in proceedings of an unscientific character. Further, and in regard to resolution (b), there can be no doubt that time and money will be saved by grouping the activities of school medical officers, and of the men in charge of the wounded in the war, with the common medical center.

In the course of the eight months—January 1 to August 31, 1918—the number of medical examinations conducted by National Service Medical Boards in Great Britain amounts to the large figure of 2,080,709; during this period 28,035 (1.34 of the examinations) applications were made to Appeal Tribunals for medical reexamination, and of this number of applications less than one-half were considered by the tribunals to rest on grounds sufficiently substantial to justify the granting of leave to be reexamined. Further, of the applicants who were granted leave to be examined by the Medical Assessors of the Local Government Board, the grading of 50 per cent was unchanged. In other words, in less than 0.4 (or between 3 or 4 cases in every 1,000 examined) of this enormous number of medical examinations is there reason to believe (so far as the evidence afforded by the organization of Appeal Tribunals goes) that the grading by the National Service Medical Board did not correctly represent the degree of physical fitness of the individual. Converted into practical terms, this result is expressed by the statement that a National Service Medical Board, working full time, and examining 25 men per session of 2½ hours, graded one man per week incorrectly. This deduction must not, however, be drawn without reservation, for mistakes are only recognized and rectified on appeal, and a good many patriotic people refused to appeal in any circumstances.

It will probably be a surprise to any one who considers these results to realize the vast bulk of the work which has been done by the medical profession since the beginning of this year, and it should be remembered that this has been done with administrative machinery which was not created until November, 1917, and during a period in which unprecedented strain has been thrown upon the profession to meet the heavy and persistent demands of the fighting forces of the crown for medical personnel, and in a country opposed to conscription as a distasteful novelty. Moreover, all the difficulties of recruiting and grading were constantly aggravated by the recurrent changes in army orders, raising the ages in response to official anxieties. No one could have any experience in grading under such circumstances, so that medicine may be congratulated on an exploit.

But there is another and less satisfactory aspect of this work, and that is the large percentage of men examined who were found not to have attained the normal standards of health and strength or to be capable of enduring the physical exertions suitable to their age. It has been suggested that the large proportion of unfit men among those examined during the indicated period could be explained by the fact that only an already fully sifted population was being resifted. But analysis of the records available contradicts this comfortable need. As a matter of fact, the men examined constituted a fair sample of the male population between 18 and 43 and a smaller proportion of the more fit between 43 and 51.

It appears that the experience of the boards medically examining women for the corps is broadly similar to the National Service Medical Boards examining men. These results, therefore, indicate unmistakably the existence of a deplorable state of national health.

It has, of course, not yet been possible to work out the details of this great mass of medical examinations, but the preliminary results indicate clearly that preventable disease is responsible for the bulk of these physical disabilities, and demonstrate the appalling ravages which our industrial activities have made upon our real national capital—the health and vigor of the population; too little food, too long hours of work, too little sleep, too little fresh air, too little play, too little physical comfort in the home, are evidently the principal factors concerned in bringing into existence this mass of physical inefficiency, with all its concomitant human misery and direct loss to the state. To take effective measures on the broadest lines to remedy this condition of things is the first and urgent duty of the state directly the war ends; no consideration is more important than the physical welfare of our human stock, and though real improvement can hardly be expected for two generations, the foundations of this improvement must be laid at the earliest possible moment.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

SOLDIERS' MAIL—LIBRARY FOR THE ARMY IS GROWING—FRENCH GENERAL PRAISES AMERICAN RED CROSS WOMEN—SHOWER BATHS ON THE BATTLE LINE—KNIGHTS OF COLUMBUS ACTIVITIES—DIFFERENT VARIETIES OF COURAGE.

PARIS, September 10, 1918.

THERE has been no end of trouble and of complaint since the first soldier landed in France over the wanderings and delays of mail addressed to the troops, many of the boys being months without a word from home, and on one occasion a soldier showed me seventeen letters received in a bunch, some dated seven months previously. Congressman Siegel has come to France expressly to look into the cause of these delays and correct them. In a recent talk he not only pointed out some faults that lie with the writers of letters at home, but equally gave some most excellent advice to these writers and voiced a complaint that is not infrequent among the rank and file. Part of the trouble, he said, is due to the fact that letters are misdirected. He added that the people at home must be brought to realize the importance of interesting and cheering news. This "I am worrying to death because I have not heard from you" stuff doesn't help the morale of a soldier, he said. Delivery of letters from chaplains, members of the American Red Cross, and others to families of American soldiers killed overseas, re-

counting the circumstances under which the men died, is to be expedited under a plan announced by General Pershing. Hereafter such letters will be marked with a small cross, so that they can be distinguished immediately and forwarded to the Adjutant-General's office in France. After verification of the deaths by the casualty section, they will be forwarded to the addresses.

The Overseas War Service of the American Library Association has been developing steadily, and reports submitted to the Commander-in-Chief show that up to August 1 more than 400,000 books have been shipped from America for the use of A. E. F. Of these 69,000 have been placed in Y. M. C. A. huts, Red Cross hospitals, Salvation Army cabins, Y. M. C. A. hostess houses, officers' clubs, on hospital trains, and directly with individual units—a total of more than 300 points having been served in this way. In addition to this, approximately 100,000 books have been brought ashore from the transports by the men themselves, 25,000 volumes have been delivered to the Red Cross, and about the same number to the navy for the equipment of naval stations. American troops in England are also being served. The chief difficulty has been, of course, the question of transport, but this is being adjusted, and within the last few days more than 500 cases of books have been delivered to the warehouses, so that the outlook for an increasingly valuable service is very bright. The aim to build up for the A. E. F. in France an organized library service, which will consist not only of an adequate supply of lighter reading, but will enable any man wishing to pursue special studies to get the books he needs to do so. One feature of this special book service will be its extension to American prisoners in Germany, at whose disposal 1,100 books have already been placed.

General Gouraud, commanding the Fourth French Army, has sent a letter to the American Red Cross, paying this high tribute: "The battle affords me the opportunity of extending you my deep appreciation of the great services rendered by the American canteens in my Fourth Army. No small share of the success of our arms is due to the comfort, moral and material, they have brought to our soldiers. I refer not only to Miss Knott's canteen for permissionnaires at Châlons, but also to Miss Ely's canteen at Saint-Rémy-sur-Bussy, whose beneficial influence is felt throughout the Army Corps. Kindly express my gratitude to all those whose generosity has supported the canteens, and accept my distinguished salutations."

For the first time in the war the fighting men have been provided with means for bathing, even on the edge of the battlefield. This feat has been accomplished by the medical organization of one of the American Expeditionary Force Divisions which was most hotly engaged in the July-August fighting. A report from the division urologist, after describing the equipment, consisting of forty-eight shower heads and a disinfector by which the soiled and vermin-infected clothing is sterilized, says that even with this meager equipment we have been able to keep the fighting men in good condition. At the bathing center we can bathe 1,200 to 1,500 men per day. During the present offensive we averaged 1,027 men per day. As they were relieved from the line they were either marched to the baths or transported by camions, and every man was given a good hot bath and change of clothing. The last four days of the week 5,643 men and 137 officers passed through the baths, 28,679 pieces of clothing were issued, 11,967 pieces disinfected, and 2,700 shipped to the laundry. The effect on the men was wonderful. They came back, worn out, dirty, clothing torn, and left the baths splendid, bucked up, both physically and mentally. As most of these men had to go back into the line a few days after coming out, one can appreciate the value of a bath and complete change. During the artillery preparation for the attack the barracks and trucks were struck by pieces of bursting shells, but were not materially damaged. A further development of the battlefield bathing is contained in the concluding paragraph of the report which forecasts the day when an automobile-carried shower bath will be as familiar a sight in fighting areas as the Red Cross Ambulance is now.

After a tour of the Western front to observe conditions, with a view to enlarging the scope of work of the Knights of Columbus with the United States Army, Dr. Edward W. Buckley, supreme physician of that order, and James J. McGraw, a supreme director, have returned to America. Before leaving France the two officials of the K. of C. stated that they had made arrangements for placing workers in many sections of France, and also at some of the camps in England and in Italy. Every effort will be made to help the men at the front first, as it is realized that they are the ones who should be aided before all others. More secretaries and supplies will be rushed over to carry on the work here. Mr. George Clemenceau, the French Premier, received Dr. Buckley and Mr. McGraw during their visit. They visited the most active sectors of the fighting fronts and some of the largest military hospitals. Both men expressed their admiration for the spirit shown by the American troops.

Dr. Buckley said he had never seen greater fortitude displayed than by the American wounded. In his visits to the hospitals he had talked with many of them, and the predominant idea with all appeared to be to get back to the front as speedily as they could for another try at the Boche.

At the hospital yesterday a lieutenant who has lost both his legs in the battle received a package from his wife. In it were six pairs of socks. Raising himself as best he could in the cot, the lieutenant said: "Say, boys, what am I going to do with these now?" A few minutes later Commissioner Joseph Scott, of the Knights of Columbus, who was working as a volunteer stretcher-bearer, lifted up a stretcher with a badly wounded man on it. The "blessé" opened his eyes for a minute and said: "Say, am I dreaming or are you Joe Scott, of Los Angeles?" The wounded man was Private William Kelly, a college mate of Mr. Scott years ago back in far-off California.

The men in those hospitals are the gamest I have ever seen. I have never heard a whimper from one of them yet, and it takes a lot of pluck

and courage to deny yourself a grouch against your luck and a complaint against your suffering. There are several varieties of courage, and one of the greatest is that kind found in the hospitals. In my three and a half years' hospital service I have seen many men die and I have yet to see the first one who made a fuss. One or two instances will fairly illustrate the conduct of all.

A sergeant was brought in at two o'clock in the morning, walking from the ambulance with the aid of the two orderlies to the operating room. When he was stretched upon the table I found a half-dozen small perforations made by shell fragments in his back. They looked superficial, he asserted that he did not feel badly, and with a first dressing was put to bed to await an *x*-ray examination in the morning. Not being content with the condition of his pulse, I told the nurse to keep an eye upon him, and went to my camp bed. At about four-thirty the nurse awakened me, asking that I come and look at the patient. "Does he complain?" "No, I asked him if he would like a drink or anything and he said 'No, thank you,' but I don't like the way he looks." I went to the bed, which happened to be the end bed in the corner, and found my soldier with his face to the wall. Placing my hand on his shoulder I inquired how he felt. No reply. Bending over and looking in his face—he was dead. The following day, examination disclosed a perforation of the kidney and liver in this man who did not complain. It is a wholly different quality of courage in action on the field, and in bed, in the dead of night, alone with God.

The ambulance rushed a young soldier to the hospital with a ragged hole in his abdomen. He was operated upon immediately; we have come to think no case too desperate to try to save. The boy was intelligent, knew his desperate condition, and brought all of his will to bear in the effort to win; but late in the evening the nurse came to say he asked to see me and by her face I knew—strange how these nurses get to read the unfailing signs on the human countenance. As I came in sight of the bed the boy held out his hands for me to hurry. I took his hands and bent over him, looking in his eyes, holding that light that comes but once. "Tell them, Major, I did my best"—"I will, my boy." His hands relaxed and for one moment his eyes looked far beyond, then with one convulsive effort he sat up, brought his hand to salute—"Au revoir, mon Major," and he was gone.

2. The Endobronchial Treatment of Bronchiectasis and Bronchial Abscess.—Emil Mayer describes a method of treating hypersecretion in the bronchi by suction, by washing out the abscess and applying medication through the bronchoscopic tube. The apparatus employed was devised by Dr. Sidney Yankauer and consists of a double tube, the outer one to be attached to the suction apparatus on the left and the inner one to the irrigating apparatus on the left. The method of treatment is as follows: A hypodermic of half a grain of morphine with atropine should be administered half an hour before treatment is begun, followed by thorough cocainization, with cotton applicators, of mouth, tongue, pharynx, and larynx, from ten to twenty per cent. The patient should lie on his back with his head supported by a trained assistant, the bronchoscopic tube inserted, and a spray of two per cent. cocaine and adrenalin thrown into the bronchus to allay coughing. The excessive secretion in the bronchi is then withdrawn through the tube, by the suction apparatus, and ten ounces of warm salt water slowly introduced through the inner tube is at once withdrawn through the outer one. This method is to be used in the first or second bronchoscopy. The patient, showing no intolerance to the introduction of the fluids, finally receives a solution of iodine and carbolic acid (iodine two drams, carbolic acid fifteen mm. to one pint of water) in place of the salt water. This method of treatment was repeated twice weekly in each case, with no serious results. As it may be necessary in some of these cases to continue treatment for years and in view of the danger of developing drug habits through the repeated use of morphine and cocaine, Mayer gives the treatment once instead of twice weekly. He has also drawn up a form of chart which shows the treatment given in each case, the number of patients treated each day, and the number who receive a given form of treatment. Dichloramine-T in the form of chlorazene tablets, beginning with a solution of one tablet in ten ounces of water, was given in a few selected cases, the bronchus being first washed out with the salt water. The cases reported have been under observation for three months; there has been almost complete cessation of odor, especially after the use of iodine, and a diminution in the amount secreted—at least, expectoration is very much easier. Moreover, a decided improvement has been noted in the physical condition of the patients. Mayer adds that the report submitted is one of distinct progress and he believes that the ability of the bronchi to withstand the introduction of quantities of fluid without harm has been demonstrated. This preliminary account of the work has been made in the hope that some other drug or method may be suggested that will prove even more efficient.

2. Cerebral Edema from Pressure.—W. A. Jones discusses general cerebral edema as a frequent accompaniment of many of the somatic disorders, the most common probably being a chronic nephritis or the triad of heart, kidneys, and blood vessels. He then takes up the various theories of edema of the brain and the occurrence of localized edemas. This author cites at some length three cases in which recovery resulted from a decompression operation and points out that: (1) There are undoubtedly many cases of local or generalized edema that are unsuspected; (2) Patients who give a history of an injury, however remote, provided it is localized, may have a local cerebral edema from pressure and from a fracture of the internal table of the skull, or from simple concussion of the brain, or a blow on the head, with or without infection; (3) Occasionally cases exhibiting focal symptoms may be wholly due to a localized edema, and too few cases of epilepsy, acute and violent but with transitory mental excitements, justify an exploration for a suspected edema; (4) There are many cases of hard, thick skulls, obstructing free circulation in the pia-arachnoid and in the cortical veins and perivascular spaces, which may be temporarily or permanently relieved by decompression operations. Dr. Jones's paper, which was read before the Section on Nervous and Mental Diseases at the Sixty-ninth Annual Session of the American Medical Association, was discussed. Replying to the discussion, the author stated that, in his opinion, decompression was absolutely justified in ill-defined conditions in the cortex and meninges. It was possible that local troubles might be responsible for epileptiform attacks, and such cases might safely be decompressed.

3. Etiology of Thrombo-Angiitis Obliterans (Buerger).—Willy Meyer. (See MEDICAL RECORD, June 29, 1918, p. 1142).

3. A Case of Sudden Death After an Anesthetic in a Latent Case of Shell Gas Poisoning.—Major Philip Turner reports a case in which sudden death took place, after operation, in a patient who had been gassed. The patient was admitted to hospital suffering from an infected wound of the right foot received the previous day. His general condition appeared satisfactory, though there was slight anemia and pyrexia; there was no mention of gas poisoning, nor did the patient complain of any such symptoms. *X*-ray examination revealed a metal fragment in the wound, and operation—which was a trivial one—was done the following day; anesthesia was light. After the operation, when the patient was about to be removed from the operating room, it was noticed that he had become cyanosed and was straining as though about to vomit. The anesthetist remained with him and he recovered, sat up, and spat out some mucus; pulse was unaffected. Instruction was then given to take the patient back to his ward, but within three minutes he collapsed. Attempts at resuscitation were commenced immediately and kept up for an hour, but there was no response. Post-mortem examination made the following day showed that the whole heart was dilated, especially the right auricle and ventricle; valves were competent. There was no evidence of any vomiting having occurred and no obstruction in air passages. Tracheitis was present and was especially marked just above the bifurcation. The lungs were slightly congested and edematous, particularly at the bases. The stomach was nearly empty and other viscera normal. The whole appearance was characteristic of gas poisoning, probably phosgene. Death was due to primary cardiac failure. The author considers it probable that the patient made some slight muscular effort and thus threw too much strain on a dilated, weakened heart. He points out the lesson to be learned, that where there is any suspicion of gas poisoning, patients should be kept strictly in the horizontal position after an anesthetic and that every movement should be checked.

1. Report on the Essential Characteristics of Successful and Unsuccessful Aviators, With Special Reference to Temperament.—Captain T. S. Rippon and Lieutenant E. G. Manuel, a medical officer stationed at an aerodrome and a pilot of 600 hours' experience respectively, give the results of their first-hand observations as to the characteristics of a successful aviator. They have studied the life history of efficient pilots and have found that they possess the following characteristics: resolution, initiative, presence of mind, sense of humor, judgment; almost without exception they are keen sportsmen, of an alert, cheerful, optimistic happy-go-lucky disposition, full of animal spirits and vitality, and frequently lacking in imagination. Their favorite amusements are the theater, music (ragtime), cards and dancing, and the authors believe that a riotous evening once or twice a month is necessary for the average pilot. The fit pilot requires no stimulant and is fully aware of the danger of taking too much alcohol; he therefore rarely touches it. Older men with "nerves," however, take it freely, and the authors state that it is beneficial in so far as it enables a man to sleep after an exciting day and promotes good fellowship in the mess. Marriage, because of the sense of responsibility and consequent fear of accident, is a disadvantage to the pupil under instruction and, in most cases, to all flying men. One of the most important characteristics in successful aviators is "hands"; the pilot with good hands senses unconsciously the various movements of the aeroplane and rectifies abnormal evolutions; he anticipates "bumps" and invariably is a graceful flyer. Good hands appear to be congenital and cannot be acquired. The authors have produced a mechanical contrivance for the purpose of demonstrating the difference between light and heavy handed pilots, with which they are experimenting. The fighting scout is usually the enthusiastic youngster, full of the joy of life, of average intelligence, keen on flying, and with little knowledge of his machine or engine, little imagination, no sense of responsibility, a keen sense of humor, "hands," and quickness of thought. The less he knows about the mechanism of his machine the better, as a realization of the strain put on the machine at times might cause him to lose his nerve. Rippon and Manuel suggest that every medical examination of a prospective aviator should be preceded by a few minutes' conversation to ascertain the temperament or make-up of the individual. A healthy mind is the first essential. The possession of a suitable temperament is

the criterion of the individual's ability to fly, while the possession of a suitable physique is the indication whether he can fly to great heights and stand the strain of continuous flying. A suitable physique without the temperament required means failure, whereas many men physically unfit have become successful aviators. The following physical disabilities have been noted in temperamentally unfit pupils: stammering, minor defects of vision, adenoids or nasal obstruction, poor peripheral circulation, loss of tone (soft and flabby muscles, moist and cold hands, pale complexion, stomach splash, etc.); the authors, however, do not suggest that any one of these defects necessarily disqualifies a pilot. Lieutenant Manuel adds a note on the strain of flying, especially in cross country flying and at the front. He points out that inability to stand heights is often due as much to psychological causes as insufficient oxygen.

2. The Value of X-rays in the Treatment of Malignant Disease of the Breast.—Claude Saberton considers first the case of the patient sent for prophylactic treatment following operation. Such cases should be sent to the radiologist as soon as possible and it is essential that large doses of *x*-rays be administered, the rays being measured after filtration through 2 or 3 mm. of aluminum. The scar area, axilla, supraclavicular and post-scapular areas should all be treated and, with careful technique, the doses can be repeated to the same skin areas once a fortnight. This method enables a large quantity of rays to reach the mediastinum. Radiation is facilitated by introduction of the Coolidge tube. The first course of treatment lasts about three months; a second shorter course is given after two or three months, and subsequent radiations are administered at gradually lengthening intervals, the patient being kept under observation for two or three years. During this time blood tonics and, in some cases, thyroid extract should be given, and the patient cheered and encouraged as much as possible. Saberton emphasizes particularly the importance of optimism. The results to be obtained from this treatment are: (1) The patients are less likely to have a recurrence than those not so treated; (2) Local recurrence in the scar area is rare; (3) Supraclavicular deposits do occur, but, as a rule, can be controlled; these deposits never break down or ulcerate; (4) Mediastinal recurrence appears to be less frequent; (5) The general health of the patient is improved. In view of these facts every case of scirrhus mammæ should be subjected to efficient *x*-ray therapy as soon as possible after operation. The author does not consider operation advisable in slow-growing atrophic scirrhus mammæ in patients about 50 years of age. In recurrences the special circumstances of each case must be considered, but the results of radiology are often unexpectedly good. Saberton then discusses the treatment of inoperable growths, all of which should be given the chance of deriving benefit from *x*-ray or radium therapy. He points out that it is impossible to tell how a patient will respond to radiation. For cachectic patients little can be done beyond giving relief from pain. Blood examination is helpful, and the thorax should be examined from time to time for secondary deposits. Malignant growths are affected by radiation directly and indirectly through the reaction of the patient, and research has shown that cells in process of rapid division, lymphoid tissue, and the endothelium of the blood vessels are especially vulnerable to radiation. It is essential that treatment should be pushed in massive doses to the limit of, or even beyond, skin endurance, as small doses stimulate cell growth. An important guide is the amount of constitutional disturbance following intensive therapy; the author has known patients have a temperature of 102° or 103° for weeks. In conclusion, Saberton draws attention to two rare conditions which arise as a result of radiation. They are: (1) Late *x*-ray reaction, when the skin and subcutaneous tissue become very tough and finally slough. This may develop weeks or months after patient has ceased treatment, and is very painful and slow to heal. (2) Anemia, which is probably of the same type as that which sometimes develops in *x*-ray operators, as it is known that *x*-rays have a profound effect on the blood. In inoperable cases, therefore, the *x*-rays are of undoubted therapeutic value. Life is prolonged, and growths robbed of their most distressing features; pain is relieved or alleviated, secondary infected glands can be controlled and prevented from ulcerating, and the primary growth often shrivels or remains *in statu quo*. Inoperable growths occasionally become operable and the mental comfort derived by the patient would alone justify the treatment. In some cases, Saberton considers that surgeons might with advantage employ electrothermic coagulation.

7. The Treatment of Irritant Gas Poisoning.—Captain J. M. Lazenby describes a method of treating cases of irritant gas poisoning with symptoms of acute catarrh of the mucous membranes of the eyes and of the respiratory tract. He has found that success depends entirely on the care with which this method is carried out and the frequency of the treatment. A warm solution of sodium bicarbonate—10 grains to the ounce—is made, and a compress of gauze wet with this solution is placed on the eyelids in severe cases when the eyes are closed through photophobia or dried secretion. When the eyelids are unsealed, the margins of the lids are bathed till all crusts can be wiped away. A Carrel syringe is then filled with the solution, a few drops instilled into the eye, and the lids closed. This is done about four times, till all secretion has been washed away; the skin is then dried with cotton wool. In mild cases the eyes may be left uncovered except by the eye shade; in severe cases another compress covered with jaconet is bandaged on lightly. A little vaseline is smeared on the skin to prevent irritation from the discharge. In respiratory cases a spray is half filled with solution. Patient sits up and gargles his throat and mouth with the solution; he then opens his mouth wide and breathes in and out, the spray nozzle being held an inch from the mouth and the jet directed to the back of the throat. (The patient must sit up and respire during spraying). Spraying must cease when the patient wants to spit out, and the operation must be repeated four times. Patients should be treated every three hours, and when cases are numerous they should be instructed to carry out the treatment for themselves, using a bath for the eyes instead of a syringe. It is advisable to isolate patients suffering from gas poisoning, as other patients near them always suffer from irritation of the throat and cough. The procedure described diminishes or completely relieves photophobia, and greatly relieves pain, although catarrh of the eyes persists. In throat cases, purulent mucus is expectorated, the dry cough becomes loose and pain in chest is lessened. Soreness of throat usually persists. The chief benefit is relief from cough and, consequently, possibility of sleep. The best results have been obtained in cases from three to six days old. As the treatment has been carried out only on board ship, the author is unable to say whether the results are permanent; he believes, however, that if this treatment were given continuously from the beginning, the period of convalescence would be materially shortened.

Berliner klinische Wochenschrift.

August 12, 1918.

Wounds and Surgical Affections of the Kidneys.—H. Kümmell passes in review the modern procedures of renal exploration. He particularly insists on the use

of cryoscopy of the blood (consequently adopting the teachings of the French school). War surgery has shown Kümmell that renal lithiasis is more common than was formerly suspected and operation is the only way to cure it, on the condition that local anesthesia is made instead of general narcosis. Vesical tuberculosis is *always* the consequence of renal tuberculosis. But when tuberculosis of the bladder and genital organs exist together there is a primary renal lesion and also one in the genital organs.

An Epidemic of Diphtheria from Food Infection.—Gobernheim and Nagel report an epidemic in a military camp, the development of which would seem to indicate that the infection was conveyed by means of food because several kitchen hands had suffered from the disease before it assumed an epidemic form. Two other regiments, stationed some distance off, were also infected. Their food was sent them from the same kitchen.

Berliner klinische Wochenschrift.

August 19, 1918.

Radiological Experiments with the Antituberculous Remedy of Friedmann.—M. Immelmann offers an article essentially consisting of a series of cases summarily reported, showing the patient's status before and after this treatment. From *x*-ray examination, he thinks, it results that the action of the remedy is very efficacious, both in pulmonary tuberculosis and tuberculous bone lesions.

Follicular Dysentery and Cystic Colitis.—M. Löhlein replies to Orth's paper (see MEDICAL RECORD, p. 604). He denies the majority of Orth's conclusions and is particularly fierce in his argument against Orth's division of superficial cystic colitis and deep-seated cystic colitis. Löhlein has never met with a purely typical case of the former process and maintains that it is always deep-seated.

The Formation of Grafts in Destructive Wounds of the Fingers.—Guetsch endeavors to form a graft for two fingers, the thumb and auricular, by excision of the three middle fingers and their metacarpal bones. A double flap assures the covering over of the wound. The muscular structure of the first and fifth fingers is to be particularly preserved because after the operation it will permit the patient to seize objects such as pencils, broom-handles, etc.

Münchener medizinische Wochenschrift.

August 13, 1918.

The Reliability of the Wassermann Reaction.—K. Ziegler considers the reasons why the medical profession no longer believes in the reliability of this diagnostic means. Confidence has been shaken as much by research work, which has shown its lack of specificity, as by articles which have shown the discord which exists between the results of different laboratory findings for the same sample of blood submitted for the test. The writer refers more particularly to the technical side of the question, to the original rules laid down by Wassermann and which are not strictly adhered to by many laboratory workers, as well as the changes in technique advocated by some, as Kaup, for example.

The Effect of Turpentine Injections on Suppuration and Inflammation.—V. Klingmüller has continued his essays on the therapeutic utilization of turpentine injections (20 per cent oil solution, intragluteal injections of ¼ c.c. of the pure drug). He has obtained appreciable results in gonorrheal complications, furunculosis, various forms of dermatoses, and renal and pyelitic affections. Turpentine causes a marked polynucleosis in the blood. The writer's discussion of the probabilities of the mechanism of the action results in highly speculative considerations of no practical value.

Sauerbruch's Artificial Arm.—Biesalski makes his amputation patients exercise with Mosso's apparatus before applying a prothesis. He has noted that the most difficult movement to execute is the slow and complete relaxation of the muscles of the arm. This relaxation is just the necessary one for patients to acquire a more extensive field of motion when the prothesis is applied. His experiments have led the writer to add a mechanism to Sauerbruch's artificial arm (an already very complicated awkward apparatus) which puts the muscular stumps on the stretch, thus attempting to realize certain conditions of normal muscular work.

Deutsche medizinische Wochenschrift.

August 15, 1918.

Wassermann's Reaction and the Biological Phases of Syphilis Considered from the Therapeutic and Prophylactic Viewpoint.—A. von Wassermann points out the importance of dealing with syphilis during its local stage which is characterized by the absence of the author's reaction. This biological phase is in opposition to the phase of metastatic reaction, characterized by a positive result. Wassermann believes it necessary to do away with the confusion often made between the biological phases and the clinical phases of the disease (primary, secondary, tertiary), which do not correspond to any special reactivity of the organic fluids.

The Malignancy of Cancer.—F. Blumenthal offers an interesting study on the present knowledge of the reactions occurring between cancerous and normal tissue. Recent studies have shown that cancerous cells secrete atypical ferments, and these ferments explain the destructive evolution of the so-called malignant growths. Blumenthal refers to certain peculiarities of cancer cells, for example, their resistance to peptic digestion while the pancreatic juice digests them perfectly. The writer considers the process of cancer as an anaplasia consisting of an autonomous change in the physiological properties and vital manifestations of the cell.

Is Ovarian Transplantation of Practical Value?—F. Unterberger believes that there are two indications for transplanting ovaries, namely, (1) in benign bilateral ovarian tumors in which resection of the growth is impossible, and (2) in serious chronic affections of the adnexa, particularly pyosalpinx with adhesion of the ovaries, when conservative treatment cannot be resorted to. The writer grafts bits of ovary in the anterior abdominal wall between the rectus muscle and its anterior sheath. The effect of the procedure is the return of the menstrual function and at the same time to establish an equilibrium of the various endocrine secretions.

Wiener medizinische Wochenschrift.

August 17, 1918.

A Procedure for the Relief of Irreducible Hernia.—J. Neumann proposes in cases of irreducible inguinal and femoral hernia to proceed with the reduction of the intestinal loops as far as the neck of the sac by pressure with a finger introduced into the vagina or rectum. A sort of aspiration of the gas contained in the gut is thus produced. Neumann thinks that every case of irreducible inguinal hernia should be treated by this procedure.

The Treatment of Gonorrheal Ophthalmia with Milk Injections.—L. von Liebmann does not hesitate to declare that "this procedure allows us to cure, with a probability almost attaining certitude, all cases of ocular blenorrhea without any durable damage and in a short time, as well as to free the patients from all contagiousness." The effects of the treatment are: (1) Disappearance of the gonococcus; (2) cessation of the discharge often after a single injection; (3) an arrest after one or two injections of the chemosis while at the same time the ulceration resulting from the chemosis is prevented from developing, or if already present is arrested in its progress, and (4) conjunctival hyperemia may persist for four to five weeks after the injections. In certain cases, the writer even claims to have observed a very noticeable improvement in the genital status.

Clinical, Etiological, and Epidemiological Observations on the So-Called "Spanish Disease."—L. Schmidt states that he has been able to grow a bacillus possessing the characters of Pfeiffer's organism. On the other hand, he has noted the frequent presence of an ocular catarrh containing the Koch-Weeks bacillus, which leads the writer to assume the identity of both bacteria and a common etiological part played by them in the pandemic of influenza which is now raging throughout the world.

Book Reviews.

DISEASES OF THE HEART. Their Diagnosis, Prognosis, and Treatment by Modern Methods. With a Chapter on the Electrocardiograph. By FREDERICK W. PRICE, M.D., F.R.S. (Edin.), Physician to the Great Northern Central Hospital; Assistant Physician to the National Hospital for Diseases of the Heart, London; Late Lecturer on Polygraphic Methods at the Medical Graduates' College and Polyclinic; Physician and Honorary Pathologist to the Mount Vernon Hospital for Consumption and Diseases of the Chest, and Examiner in Medicine at the University of St. Andrews. Price, $7.50. New York: Oxford University Press, American Branch, 1918.

OUR knowledge of the heart and its actions in health and disease is advancing with such rapid strides that a new book, if well written by one of ability and authority, is welcome. Dr. Price is well known for his work in this branch and by this work has earned for himself a position in which he can command the respectful attention of all fellow workers in the field. It was with pleasurable anticipation therefore that we opened this new book, and we were not disappointed.

The book is eminently practical, even though treating of so theoretical a subject as much of the modern graphic study of heart disease is, for it not only deals with the newer knowledge for which the medical world is so largely indebted to Sir James Mackenzie, but also treats of the older methods of diagnosis and treatment the value of which has in no way been impaired by the modern methods of study. There are chapters, of course, on the pulse and on blood pressure, and an excellent one at the end of the book on electrocardiography. Dr. Price has written a work admirably adapted to the needs of the student and general practitioner and one from which even the specialist in cardiology can get suggestions that will aid him in his progress in this difficult though fascinating field of study. The book is clearly printed, sufficiently illustrated, chiefly with pulse tracings and cardiograms; well bound, and of a convenient size for study and reference.

MILITARY SURGERY OF THE ZONE OF ADVANCE. By GEORGE DE TARNOWSKY, M.D., F.A.C.S., Surgeon to Cook County and Ravenswood Hospitals, Chicago; Major, M.C., U.S.R., American Expeditionary Force, France, 1917-8. Medical War Manual, No. 7. Price, $1.50. Philadelphia: Lea & Febiger, 1918.

THIS little volume comprises twenty-eight chapters devoted to such varied subjects as general pathological processes, as shock and tetanus; local injuries, as those of the cranium; causal agencies, as projectiles and gas; non-bloody traumas, as burns and freezes; diagnostic subjects, as bacteriology and radiography; general and special treatment of injuries and wholesale military surgery, at regimental first aid stations. There could be but one objection to this elastic method of grouping, to wit, the likelihood of repetition; but that is readily avoided and not to be thought of in a work intended for a concise pocket manual.

THE DIAGNOSIS AND TREATMENT OF VENEREAL DISEASES IN GENERAL PRACTICE. By L. W. HARRISON, D.S.O., Lieut.-Colonel, R.A.M.C.; Lecturer on Venereal Diseases and Officer in Charge, Military Hospital, Rochester Row. Price, $7.50. New York: Oxford University Press, American Branch, 1918.

HOWEVER interesting may be the subject matter of a book, much of its charm is lost by a jumbled arrangement of its contents. In this work the reader's attention is pulled hither and thither by a lack of sequential discussion of each of the venereal infections. The chapters on syphilis are comprehensive and instructive, and especially commendable are the chapters on syphilis of the nervous system. Chapter XVI on technique of taking specimens and the methods of their examination and Chapter XVII on the interpretation of laboratory reports are praiseworthy because of the lack of presentation and discussion of these important subjects in contemporary works. In those chapters dealing with gonorrhea the author omits many acceptable instrumental methods of diagnosis and treatment, such as the posterior urethroscope and cystoscope, nor does he mention those occasional annoying sequelæ of chronic gonorrheal prostatis such as sexual impotence, defects of ejaculation, etc. In all other regards the teachings therein contained are orthodox and acceptable. The illustrations have been judiciously chosen and mechanically well executed.

NURSING TECHNIC. By MARY C. WHEELER, R.N., Superintendent of Illinois Training School for Nursing. Price, $1.50. Philadelphia and London: J. B. Lippincott Company, 1918.

FOR those unfamiliar with the subject it may be stated that nursing technique comprises housekeeping (wards and private rooms), beds, baths, care of the patient, medicine and nourishment, dressings and the dressing room, collection and preparation of specimens, emergencies, and unclassified—the latter comprising fire prevention, admission and discharge of patients, night nursing, handling of groups of injured, etc., etc. Certain subjects, like cooking for the sick, menus, recipes, etc., find no place here. The information in the present work is conveyed wholly as discrete memoranda and agenda in the attempt to standardize the subject matter. This arrangement doubtless facilitates memorizing and automatic performance of duties.

L'UTILISATION MÉNAGÈRE DES FRUITS SANS SUCRE. Par A. TRUELLE, Publiciste Agricole, Membre de l'Académie d'Agriculture de France. Price, 2 Francs. Paris: Masson et Cie, 1918.

THE subject matter of this pamphlet of 96 pages is as follows: Simple conservation of fruits without preservatives; use of sulphurous acid; preparation of fruit juices; dried fruits; fruit jams and the like; brandied fruits; "raisined" fruits; fruit syrups; fruit jellies; ciders, etc. The closing chapter is devoted to fruit growing as it bears upon home conservation of fruits. The American reader will doubtless be struck with the slight reference to berries, which play so large a rôle in the home canning industry.

THE ESSENTIALS OF MATERIA MEDICA AND THERAPEUTICS FOR NURSES. By JOHN FOOTE, M.D., Assistant Professor of Therapeutics and Materia Medica, Georgetown University School of Medicine; Instructor in Materia Medica and Therapeutics, Providence Hospital Training School for Nurses. Third Edition, Revised, Enlarged, and Reset. Price, $1.75. Philadelphia and London: J. B. Lippincott Company, 1918.

THIS, the third edition of a very useful reference book for nurses, has been thoroughly revised in conformity to the standards of the U. S. Pharmacopeia IX. Revision. Also a good deal of new matter has been added, notably condensed information concerning the newer antiseptics used in European military surgery. The drug classification has been rearranged and in every respect the work has been brought up to date. It may be recommended as a practical text-book for nurses of great merit.

THE SERIOUSNESS OF VENEREAL DISEASE. By SPRAGUE CARLETON, M.D., F.A.C.S. Price, 50 cents. New York: Paul B. Hoeber, 1918.

THIS tiny volume is a reprint of a limited edition arranged by Dr. Carleton as a gift for the use of Base Hospital No. 48. It consists of twenty-six illustrations, with explanatory paragraphs of venereal infections in their most violent forms. It is a pictorial warning to venereal sufferers to obtain competent, early, and persistent treatment.

DIABETIC COOKERY. Recipes and Menus. By REBECCA W. OPPENHEIMER. Price, $2. New York: E. P. Dutton & Company, 1918.

THE author is a diabetic who has spent eight summers at Carlsbad and Neuenahr, where many diabetics have been successfully treated. Her book is based on the dietetic plans carried out at those resorts, somewhat modified for the American public. It will be found useful by those whose difficult task it is to care, in their own household, for patients who are weary of the monotony of their diet and who would welcome a variety in the mode of preparation of their food, even if they cannot have a great variety in the foods themselves.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 17, 1918.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS meeting was devoted to an informal discussion of influenza and of the present epidemic.

Dr. ROYAL S. COPELAND, Health Commissioner of New York City, opened the discussion by describing the measures adopted by the Health Department to meet the exigencies of the situation. He said it was meet and proper at a critical time like the present that the Commissioner of Health should appear before the Academy of Medicine to submit to the judgment of its members, who were among the foremost in the medical profession in this city, a report of the activities of the Health Department, and a statement of the reasons that had guided him in determining upon certain procedures and in omitting certain others which had been suggested from time to time. The Health Department had been handicapped by the fact that in consequence of the urgent necessities, warships had been admitted bringing persons affected with influenza as well as carriers. The department was further handicapped by the large number of enlistments in the military service of doctors and nurses of the Health Department staff. Notwithstanding these handicaps, the situation had been promptly and energetically met. Every function of the department which did not contribute to the prevention of the disease or to the care of sufferers had, for the time being, been suspended or subordinated. The department had taxed every available resource for the skilled and unskilled workers necessary for the operation of emergency hospitals, and was daily supplying nurses, nurses' aids, orderlies, and other helpers where they were needed. The measures adopted by the Department of Health had been widely approved and many offers of cooperation had been received. The press had been most generous in serving as a medium for the education of the people. Attempts had been made through placards, circulars, and verbal instructions in the public schools to apprise the public of the danger of close contact in public places, of sneezing, coughing, and spitting. As a result of the various measures adopted by the department, Dr. Copeland presented the fact that New York City, with its five and three-quarter million population, had had a much lower mortality rate from influenza and pneumonia during the past four weeks than was reported by any other American city at the same stage of the epidemic. The City of New York had thus far, tragic and serious as the consequences of the epidemic had been, fared very much better than other municipalities. In conclusion, Dr. Copeland stated that the Department of Health stood ready to help the medical profession in every possible way. It welcomed all helpful suggestions, all information of value, and all constructive criticism, but it required in return the assistance of the medical profession, principally in reporting cases. If any physician needed a hospital bed for a patient, or a nurse, he would save time by applying directly to the department where a clearing house had been established and from which help was being sent to all parts of the city. The department had bent every effort to make the reporting of cases on the part of private physicians complete so that it might be in possession of all the facts which would enable it to concentrate the combined attack of its own staff and that of the social agencies in those districts in which the disease was most prevalent. An Emergency Advisory Committee had also been appointed consisting of representatives of the New York Academy of Medicine, the Red Cross, the various nursing activities, the Merchant's Association, and other organizations interested in social welfare, which would assist in solving problems connected with the epidemic as they arose.

MAJOR DUDLEY ROBERTS, M.C., U.S.A., of General Hospital No. 1 (Columbia War Hospital), said he was very glad the President of the Academy had spoken of this as an informal discussion because it was impossible at a time like this to form positive conclusions so we must hazard tentative opinions. The present epidemic of influenza was important not only because of what it was just now but because it was likely to recur after it had subsided, that having been the experience abroad; also because we might expect that influenza would be more or less endemic and would therefore complicate diagnosis in many cases. It was important that we should get an idea of just what the disease was like and how pneumonia following influenza differed from ordinary lobar pneumonia. We were at first inclined to take the disease rather lightly, but as time had gone on we had changed our minds. We had not since 1889 seen a form of disease which resembled the present epidemic of influenza. It was characterized by sudden onset, dullness, headache, backache, congestion of the pharynx, and coryza. Tonsillitis was but rarely present. The patient was dull and apathetic, approaching the typhoid state, and the leucocyte count was low (between two and ten thousand), which was a valuable point in differentiating it from conditions presenting somewhat similar symptoms. There was a temperature of 102°, 103°, or 104° F. for two or three days. A case having an elevated temperature after 48 hours was suspicious of bronchopneumonia and if a high temperature persisted for over three days one might be almost certain that he was dealing with bronchopneumonia. A large series of cases had been radiographed and this had definitely settled that these cases having a continued temperature were cases of bronchopneumonia. The normal course of simple influenza was exceedingly short. The signs of bronchitis were almost always lacking. The cases that developed bronchopneumonia might be grouped as follows: (1) Cases resembling a simple influenza in which the temperature subsided in forty-eight hours and the patient did not seem to be very sick. In these cases the radiograph showed consolidated areas. (2) Cases that acted like those of group one, but after a few days had a rapid rise in temperature, a rapid extension of the process, and went on sometimes to a fatal termination. It was these cases that emphasized the importance of keeping influenza patients in bed protected from secondary infections. (3) Cases starting out like a severe influenza, with great congestion, cyanosis, and severe nosebleed, or bleeding from the vagina or rectum, or gastrointestinal hemorrhage. Some of these congestive cases improved after a few days or the process again lit up and progressed rapidly to a fatal termination. Patients with red, flushed face, or cyanosis, were very apt to get up an acute condition of the lungs, and those with cyanosis and then an apparent improvement should be regarded with suspicion, as they were particularly likely to terminate fatally. (4) Cases that from the onset were evidently fatal. He had been told of cases where a man under the eyes of a good regimental officer had died on the way to the hospital. Such patients died from the influenza infection and its effects on the circulation and the heart. (5) An important series of cases in which empyema complicated the condition. At first they did not see these patients but now they found that some were patients who lived long enough, got up empyema at the apex or in the upper part of the chest, which was difficult to diagnose except by radiograph. Major Roberts emphasized the importance of recognizing pneumonia and said that it had been their experience that physicians did not recognize influenza pneumonias because they expected the physical signs of lobar pneumonia. A high temperature persisting for more than forty-eight hours, a peculiar redness or dusky pallor, and rusty sputum, were almost pathognomonic of pneumonia. The definite physical signs of pneumonia appeared late. The first sign for which to look was the prolonged, high pitched expiration. Dullness was in itself an exceedingly unsatisfactory sign. One obtained a better idea of the condition of the lung by slapping than by percussion; with percussion there was not much difference between the sides of the chest. Crepitant râles were not heard so early or so constantly as in lobar pneumonia, since we did not have the early pleurisy as in lobar pneumonia. The first definite sign was a slight change in the whispered or spoken voice approaching bronchophony and perhaps

later a change to bronchovesicular breathing. In many cases there was not much that pointed to the presence of pneumonia until the patient was very far advanced in the disease. The process not infrequently was missed in the middle lobe. The frequency of involvement was first the lower right lobe, then the lower left, next the upper right, and then the upper left. He had seen a few cases, however, in which only the upper lobes were involved, there being no demonstrable lesions in the lower lobes. All were familiar with what had been advised in the way of drugs, and they had found nothing in the line of drugs that was of particular value. They gave digitalis to their patients at the beginning of the pneumonia and thought that was a wise plan to adopt. They had tried the vaccine because they did not know what else to do and because there were theoretical grounds for believing that it might be effective. Major Roberts exhibited charts showing series of cases treated with the vaccines and without, which afforded apparently conclusive evidence of the value of the intravenous vaccine treatment. In one series of 86 cases without vaccine the mortality was 35 per cent., while in a series of 153 patients treated with the vaccine the mortality was about 8 per cent. He felt sure that the mortality could be brought down to 9 per cent. by the use of the vaccines intravenously. The most striking fact brought out by the study of these series of cases was not that the mortality was so low, but that after the first injection of the vaccines, in cases in which there had been congestion and nosebleed, the latter stopped and there was less dyspnea and very little cyanosis except in the very severe cases. The vaccines were given in three to four doses of one-half, one, and two c.c., at 24 hour intervals. In closing Major Roberts said he felt like apologizing at this time when every one took such a serious view of the epidemic for presenting such a hopeful plan of treatment because possibly he might be wrong, but the results seemed to justify their belief in the vaccines if properly used.

Dr. ANNA M. WILLIAMS said that in making their microscopical and clinical investigations at the laboratory of the New York City Health Department to determine whether they could demonstrate a specific microorganism which was responsible for the present epidemic of influenze they had studied the germ flora from two sources. First, they had taken cultures from the upper air passages, the nose, tonsils, and pharynx, and from the blood the living patient; and, second, they had taken cultures from cases examined at autopsy. They had looked for the influenze bacillus, for a hemolytic strepticoccus, for Gram-negative, and any other organism that might be present in large numbers. In four cases at autopsy the influenze bacillus was found in large numbers in the lungs and in eight instances the influenza bacillus and the pneumococcus were found in the lungs. In three instances the influenza bacillus and the streptococcus were found in the lungs, in three cases the pneumococcus alone, and in three the streptococcus alone. In two cases the influenza bacillus was found in the heart's blood. In summarizing Dr. Williams said that the influenza bacillus had been found in large numbers in the nasopharynx of 100 per cent. of the cases diagnosed as influenza and running a severe course. It was estimated that from 10 to 20 per cent. of the cases diagnosed as influenza which ran a mild course contained no influenza bacilli. If this was true and if the *Bacillus influenzæ* was the irritating cause of the disease, these cases were diagnosed wrongly; if the cases were diagnosed correctly, then either the influenza bacillus was not the initiating cause or our methods of detecting it needed to be improved. Whether or not the influenza bacillus was the initiating cause their study gave evidence that it had a marked pathogenic action, being the only apparent cause of death in 20 per cent. of the cases examined at autopsy, and assisting in the cause in 50 per cent. more, and the evidence was sufficiently strong to warrant making a trial of the effect of a vaccine on the prevention of the disease or at least of the prevention of the severe forms of the disease.

Dr. DOUGLAS SYMMERS spoke on the pathology of influenza as observed during the present epidemic, basing his remarks on the study of 18 cases coming to autopsy in Bellevue and Willard Parker Hospitals. All of these had been acute cases, the patients dying within two or three days from the onset of the disease. The most noticeable changes were those in the lungs. He pointed out that the pleura was seldom involved as shown by exudate and that the pleural cavities almost never contained pathological excess of fluid. The lungs themselves were of a deep slate blue color and were markedly congested. In every instance both lungs were involved, the lower lobes showing more advanced changes than the upper lobes. The lesion was that of a confluent exudative and hemorrhagic lobular pneumonia. Petechial or splotch-like hemorrhages were found both in the pleura and in the pulmonary substance. The cut surface was of the smoothness of velvet, not a trace of fibrin being apparent either to sight or touch, and the trachea and bronchi were intensely congested. On microscopic examination the alveoli were found to be free from fibrin and were filled or partially filled by blood serum or a mixture of blood serum and red blood corpuscles or polynuclear leucocytes. In the upper lobes, partially or completely consolidated lobules in the process of fusion alternated with area of acute vesicular emphysema. Similar areas of acute vesicular emphysema in small numbers were found scattered through the consolidated lower lobes and were practically constant at the free edges. Dr. Symmers pointed out that these areas of vesicular emphysema were of great clinical significance. For example, in two cases rupture had occurred, producing infiltration of the subcutaneous tissues above the clavicles. In another case rupture resulted in the production of a left sided pneumotherax. Another feature which, according to Dr. Symmers, occupied a prominent place in the pathology of the prevailing pandemic influenza, was to be found in the form of diffuse acute perenchymatous degeneration of the kidneys attended by desquamation of cellular débris into the lumina of the convoluted tubules. The kidneys, like practically every other organ in the body, were intensely congested. In several cases Dr. Symmers said that he had seen jaundice due to extreme congestion and swelling of the mucous membrane of the duodenum so that it was impossible for the bile to escape freely from the larger bile ducts, being thus retained in the intrahepatic ducts and in the liver cells, and finally being diverted into the intercolumnar capillaries and thence into the general circulation. Moreover, the bile capillaries were obstructed as a result of excessive cloudy swelling of the liver cells. In two of his cases there were signs of hemorrhage from the intestinal mucous membranes caused by diapedesis of red cells associated with intense congestion. Dr. Symmers pointed out that in most of the cases of fatal influenza the right side of the heart was greatly dilated, thus accounting in part at least for the marked cyanosis which not infrequently was observed during life. He stated, moreover, that those cases of influenze which were attended by delirium were characterized anatomically by marked edema and congestion of the brain. In one of the cases observed at Bellevue Hospital the brain was the seat of an acute diffuse purulent meningitis of pneumococcal origin.

Dr. HENRY W. BERG said that they had at Willard Parker Hospital during the last five weeks about 700 cases of this epidemic. They came in at first at the rate of on one day, as many as 70 cases; more recently not in such large numbers, and certainly at the present time a larger number were being sent out cured than were being admitted. He had, however, few statistics to present at this time owing to the lack of help. The speaker was able to recall his experience in the epidemic of 1890 and it was interesting to observe the relative clinical differences in the cases. The first thing that struck one was that these cases had very few catarrhal symptoms. Attention had been called to this feature, but it was so important that it ought to be repeated that very few cases showed predominant catarrhal symptoms. All showed slight conjunctivitis and rhinitis, but the vast majority showed only congestion of the throat and upper respiratory tract. Such obviously prominent organs as the tonsils showed absolutely no inflammatory enlargement, simply redness, and they lay deep between the anterior and posterior pillars of the fauces. They showed no follicles outlined by a white area and they could not be palpated from the outside. If one found inflamed, bulging tonsils with

follicles, influenza was as a rule not present, and this was an important clinical differential feature. There were three groups of cases. One of these showed simply catarrhal symptoms, but these were in the minority. A second class showed a vast amount of pulmonary involvement, pneumonia in many cases, or scattered rales crepitant and subcrepitant, preceding pneumonia, thus showing serious trouble, and these cases all ran a temperature curve. The simple catarrhal cases ran a temperature for about five days and then subsided by crisis or pseudocrisis. The cases of bronchopneumonia never subsided absolutely to normal at this time, but subsided gradually or developed a septic curve continuing for eight, ten, or twelve days, then declining by lysis. Bronchopneumonia was most frequent, but lobar pneumonia could be made out in some cases, involving the entire lung. Third, there was a class of toxic cases which came into the institution with pneumonia well developed. Some of these came in on the third or fourth day and some on the fifth day. These cases were intensely toxic, many of the patients were delirious and all were intensely sick. These should be considered in a group by themselves. Dr. Berg said he had not seen those acute cases in which death occurred within five or six hours, but he had seen patients die on the third day. There was one symptom present in almost all cases and that was an acute agonizing pain below the sternum, the kind that patients having Asiatic cholera complained of having in their bowels, and which might be due to a toxic involvement of the sympathetic nerve ganglia in the thorax. The headache was almost exactly like that of typhoid fever, but the pulse rate and respirations were nowhere near so high as in patients suffering from other types of pneumonia and not so high as one would expect them to be to correspond with the temperature curve. The temperature curve in these pneumonia cases might be 100° to 105° F., and the respiration rate not more than 20 to 30. The respiration rate might remain below 40 until the day before death, when it would go to 60 or 70 or higher. The low respiration rate did not exclude the diagnosis of pneumonia in the presence of more or less characteristic physical signs. The most important physical signs from the diagnostic standpoint were those obtained by percussion; auscultatory signs were simply confirmatory.

Dr. William R. Williams said he had not had the opportunity of treating as many cases of influenza as Dr. Berg or Major Roberts, but he had been very much impressed by the fact that this epidemic presented a real disease entity. When one struck a disease that appeared new to him it was a good thing to go back and look up his old notes. That the speaker had done, going over notes on Dr. Delafields' lectures, and he had found that this was not a new disease but the same disease that Dr. Delafield had described. The striking point was the way in which the disease attacked the circulartory system. It was noticeable that the one condition mentioned most frequently in the discussion of the evening was "congestion" and that was emphasized in connection with whatever symptoms were noted, and at autopsy congestion was the most striking feature. There was congestion of the intestinal tract and a tremendous congestion of the skin, and other parts. What impressed one most forcibly was that the gravity of the cases often could be guessed by simply looking at the condition of the skin. On his service in the New York Hospital they had had about 100 cases and they had come in rather late, later than the cases at Willard Parker Hospital and later than those at camp. The first two cases were of soldiers who came about the middle of September. Most of the cases gave chest signs or the x-rays showed consolidation, so that one was convinced that consolidation of the lung was present. Up to the present time the mortality had been fairly high in their institution, 22 of the 100 patients having died thus far, which struck him as a tremendous mortality. Cases that were autopsied all showed most marked congestion for which there seemed to be no adequate therapeutic remedy. The condition seemed to be a generalized paralysis of the of the vasomotor system for the control of which we should have to look to some biological method and hence he was much interested in Major Robert's presentation regarding vaccine, and hoped that he was opening out the way.

Dr. Hermann M. Biggs said there was much to be said because in a way we did not know enough about the situation to say anything very definite. In a way we all realized that we were having the most severe epidemic that had visited the civilized world in a century. It was a very serious indictment to public health education if we were unable to suppress such an epidemic as this. It was known that discharges from the nose and throat contained myriads of germs and we had taken no precautions to prevent the careless dissemination of such discharges. Twenty years ago the Board of Health adopted a regulation for its Sanitary Code forbidding spitting, yet spitting was not as dangerous as sneezing and coughing, and still 90 per cent of the people did not cover their noses or mouths before sneezing or coughing. It had now been made a misdemeanor to cough or sneeze without covering the mouth or nose. Such an epidemic as the present one could be limited to a large extent by taking this precaution. In one hospital in London they were treating a variety of contagious diseases in one ward under the care of the same nurses and the same conditions, and they had no secondary infections during a period of more than two years. The diseases treated in this way included measles, diphtheria, chickenpox, etc., in which the bacilli were contained in the discharges from the respiratory tract, and if the spread of the infection could be prevented in these diseases there was no reason why it could not be prevented in other diseases of the respiratory tract which were disseminated in a similar manner, by proper measures of cleanliness and decency. In this State, just as in New England, some districts were very heavily invaded by influenza while in others there were very few cases.

Major Winders, in charge of Embarkation Ports, said that he had been from camp to camp and hospital, so he had not had the opportunity to make to study of the serious cases, but he had been to see the cases reported in Major Roberts' second series and had examined a few of them. It was very apparent from the charts and the histories of the cases that the treatment had a marked influence on the course of the disease, though he was not satisfied that the result was due entirely to the vaccines. The striking feature that he had noticed was the difference in the general appearance and condition of the patients compared with those cases seen in other camps and ports of embarkation. The toxemia and the cyanosis were not so marked, the respirations were less rapid, and the dyspnea was not anything like as marked as in other cases. The vaccines held out sufficient promise to make it worth while to follow up the matter more closely.

Major Cary of the Laboratory of Base Hospital No. 1 said that most of the cases that he had investigated at that hospital had been lobular or bronchopneumonia and not lobar pneumonia. Type IV pneumonia had been found in quite a number of cases. In some cases the hemolytic streptococcus was found. One of the very striking features was the leucopenia and the very scant leucocytosis which probably accounted for the rapid spread of the process and the diffuse involvement of the lungs. He felt that the vaccines might help; they evidently raised the leucocyte count.

Dr. Louis Faugères Bishop said he wished to say a few words which he considered very important in connection with the treatment of the circulatory disturbances of this group of pneumonias. He was an interne in the hospital at the time of the former epidemic of influenza and at that time they had this same kind of pneumonia extending throughout the lungs, characterized by intense engorgement, terminating by lysis, and very fatal. At that time it was the custom to treat it by giving the "trinity pill," of which the active principle was aconitine. This treatment was given to every patient until the heart was slowed and the pulse rate diminished, and the patients did well under it and in many cases the fever terminated by crisis and the involvement of the lungs was lessened. Dr. Bishop said he had just returned from the meeting of the First District Branch of the New York State Medical Society, where he heard several men who had large practices and wide experience in dealing with pneumonia speak most eloquently of veratrum viride. They

had unanimously agreed that given in full doses early in the pneumonia it effected a termination of the fever by crisis and the inflammation of the lungs did not extend so widely. Dr. Bishop's own experience had been only with aconitine. The men who were neglecting these old remedies were making a mistake when it came to the treatment of intense congestion of the lungs. Another point worthy of mention was with reference to edema of the lungs and the use of heart stimulants such as adrenalin which caused the arteries to contract and forced the blood into the veins. When they administered a drug that produced this effect they did no good. If they began early to employ a remedy that kept the blood in the arteries and relieved the lungs they benefited the pateint. Forty years ago the homeopaths took up aconite and used it indiscriminately and injudiciously and as a result it fell into disfavor, but unquestionably it had a useful field particularly in the treatment of pneumonia. The early use of full doses of digipuratum, as recommended by the Rockefeller Institute, was founded upon sound reasoning. He said that as a heart specialist he was being called to patients in the latter stages of the pneumonia and his impression in the present type of pneumonia was that these young vigorous hearts of the victims were not helped by excessive stimulation as they were already overstimulated by the presence of the disease, but that the rational need was the relief of the pulmonary inflammation. Under the aconitine treatment the heart symptoms at the time of depression were indeed very alarming, but the heart responded and most of the patients pulled through while practically none recovered from the general edema of the lungs that existed when the inflammation became general. Dr. Bishop said he would rather be called to help to sustain a heart that had collapsed at the crisis than one that was exhausted during the course of an increasing edema of the lungs. He knew that this was a reversion to the old idea of an antiphlogistic treatment but it seemed to him that the circumstances justified it.

Dr. E. Libman asked whether the cases of influenza that were treated without vaccine were under observation at the same time as the series which were treated with vaccines, or whether the two sets of cases overlaped.

Major Roberts said the two series overlapped.

Dr. Libman expressed the opinion that this had an important bearing on the results. There had been, during the last week, a change for the better as regards the severity of the cases of pneumonia. In addition to the cases seen in the hospital, Dr. Libman said he had seen between 300 and 450 cases of pneumonia following influenza since the beginning of the epidemic. During the first two weeks the mortality was very high. At that time there was one type of case very frequent, which had not been met with so often during the last week; this type was characterized by the expectoration of thin bloody fluid which was not frothy and contained no mucus. Nearly all of these cases ended fatally. During the past week he had been able to make a more favorable prognosis in a very large number of cases. While the results of the vaccination at the base hospital looked good, it was of great importance that further studies should be made immediately, running a series of cases without vaccines at the same time that an equal number of cases of the same type were treated with vaccines. In one of the training schools for nurses connected with one of the New York hospitals it was reported that the results of prophylactic vaccination were so poor that it had been discontinued. Possibly the failure in this instance might lie in the technicque. While there were many points to discuss in connection with the subject, only two occurred to the speaker at the moment. Cyanosis in this disease sometimes occurred early before there was any marked involvement of the parenchyma of the lung and before there was any evidence of the heart becoming markedly insufficient. He suspected that the cyanosis, in some of these cases at least, might be toxic in origin, especially as it had been found that the pneumococci could produce methemoglobin from the red blood cells and could interfere with their ability to take up oxygen. Major Roberts had referred to the atypical emphysemata and the difficulty of recognizing them. As was pointed out by Fraenkel many years ago, the emphysemata following the pneumonia of influenza were very likely to be interlobular in situation. If one could prophesy through the experience of others there would be found later in the epidemic more cases manifesting abdominal symptoms and more cases would have symptoms simulating appendicitis. It was important to be on the lookout for these cases and not to operate too early, because as a rule they should not not be operated on, though at the same time one must not for this reason overlook cases of true appendicitis occurring during an epidemic of influenza. It was probable that the pains simulating appendicitis were due to the effect of the toxin of the disease upon the sympathetic nervous system.

Major Roberts said that one c.c. of the vaccine contained one million influenza bacilli and one million pneumococci of types I, II and III, one million streptococci and one million staphylococci. They started in with one-half a c.c., and at the end of 24 hours they gave one c.c., and 24 hours later two c.c. As a rule they did not get much reaction with the one-half c.c., though there might be a rise in temperature. As a rule from the one c.c. dose they got a fairly definite reaction which was different from a non-specific protein reaction. As to the two series of cases over-lapping: As he recalled in the first 60 vaccine cases there was not any difference from the first group; then there was a period lasting for a few days when they seemed to get milder cases, and now they were getting sicker cases again. He felt that an improvement in the method would be to make the initial dose 1 c.c.; the second, 2 c.c., and the third 4 c.c. In the last few cases this had seemed to give a much quicker response.

Dr. Robert J. Carlisle called attention to the fact that for many years there had been a capsule on the market containing acetanilid and phenacetin that was widely used in the treatment of influenza. Very frequently when they got patients with cyanosis this condition was the result of treatment with these drugs and not the result of pneumonia. In this epidemic it was all right to use these capsules for a few days but they should then be discontinued.

Dr. Max Einhorn stated that he had had quite a good deal of experience with influenza at the Lenox Hill Hospital and had observed a class of cases that were quite severe and yet the patients did not complain much, but on examination one would find symptoms of lung involvement. They had also a severe type of cases with cyanosis, toxic symptoms, vomiting, and sometimes abdominal distention, which gave the impression that the patient had ascites. In some cases delirium was also present. The prognosis was bad in this type of cases. There seemed to be a sort of paralysis of the intestinal tract and some tympanites. For these cases they had tried all kinds of remedies and had come back to whiskey, and they found that many patients improved in whom it seemed that the improvement might be attributed to the whiskey.

AMERICAN ORTHOPEDIC ASSOCIATION.

Thirty-second Annual Meeting Held in Washington, D. C., April 22 and 23, 1918

Dr. John L. Porter of Chicago, President.

Orthopedic War Hospitals, Their Requirements and Equipment.—Lt. Col. Clarence L. Starr, R.A.M.C., presented this address. These organizations, he said, should be termed "orthopedic" not "reconstruction" centers. It had been found that an orthopedic hospital connected with a general hospital was satisfactory, as it enabled orthopedic surgeons and neurologists to cooperate. The administrative work of both was combined to secure economic results, and one inspector supervised both hospitals. One assistant surgeon cared for 500 patients, with one junior surgeon and anesthetist to each 100 patients. Functional cases were sent to the orthopedic surgeon for diagnosis and to detect malingering. It was found a mistake to put an orthopedic surgeon in a general hospital, as his work was sidetracked. His services could be put to good use in the clearing station behind the lines, to treat joint

lesions. In the postoperative treatment of the wounded, massage, electro and hydrotherapy had a useful place. The gymnasium was a very active part of the whole scheme. Games were found to effect the patient's cure, unconsciously, while the curative work shops tended to raise the morale of the patient. This branch of the treatment bridged the gap between hospital and civil life. The men were employed on artificial limb making, machine shop work, boot and clothing work. For this work the men were allowed to wear uniform; the hospital "blue" being simply used to discipline a refractory patient. Prolonged hospitalization and the hospital blue had a depressing effect, and the use of the uniform and the sense of accomplishment went far to restore confidence to the wounded man and to enable him to return to useful citizenship.

A Brief Description of the Work at St. Katherine's Lodge in Hyde Park, London.—Captain F. C. KIDNER, M.R.C., A.E.F., presented this paper. This beautiful roomy house, with spacious grounds, was loaned to the British Government by Mr. Solomon of New York. The hospital, although used for British soldiers was under the American Red Cross. It contained 50 officer's beds and there was always a long waiting list. The American Red Cross had entire supervision, except as regards disability decisions. The patients proved very willing and anxious to carry out treatment. The masseur employed was a blind soldier who had become expert at this work. This gift of Mr. Solomon, by placing English officers under control of an American staff, was serving as a most efficient link in the promotion of good understanding between the two great English-speaking nations.

Major J. A. HORNSBY, M.R.C., said that in the civil hospitals in this country the unanimous conclusion had been reached that when the patient entered the hospital he was entitled to treatment for whatever might ail him. If any complications arose in his condition he should receive treatment for the same. The hospital therefore had to be a general hospital. Major Hornsby said it was unthinkable that a patient with an eye condition should have to be moved to an eye hospital, yet that very thing happened lately in the large cities in this country. He knew of a case that developed pneumonia, the patient had to be moved because he could not be treated in the general hospital. In the new field upon upon whcih they were now embarking it would be found necessary to change this phase of the question. At first when it was found necessary to create an army, it was decided to take only able-bodied men. A little later certain remediable defects were noted, and the men were required to submit to operation. Later still another ruling took effect. He was more than pleased to hear Colonel Starr say that these defectives should not be operated upon. The profession should be outspoken about that and not attempt to turn the army into a curative establishment for defectives. He had been in many camps in this country and had seen men operated upon again and again to cure defects, without result. Before attempting to reconstruct defectives for active service, the available supply of men should be exhausted. The general hospitals now were for the care of diseases and injuries that had come upon men after becoming part of the military force, and the same thing should be true when they come back again. Then, if ever, they would be liable to complications of all sorts and and the hospitals should be qualified to take care of them. The hospitals did not consist in equipment or bed capacity, but in the personality of its staff. It was not a collection of instruments and beds, but a place where men were competent to take care of the sick. It was easier to get equipment than to get competent men. It had been said that only in the special hospital did one find such personnel. That might be true, but Major Hornsby said that he had taken over three or four hospitals, amounting to a capacity of 2000 beds. These would be used as general hospitals, and it was expected that the trend of the hospital would follow the capacity of the men working in it. They would be great only if associated with prominent medical men.

Major W. G. ERVING, M.R.C., said that this subject of orthopedic war hospitals introduced by Lt. Colonel Starr was a tremendous one. He thought the orthopedic hospital should be absolutely separate from a general hospital. In England experience had shown that those orthopedic centers which were doing the best work were those separated from work of other kinds. Hospitals at Hammersmith and Leeds, which were entirely orthopedic and which were equipped with 2000 beds were getting the best results. The next best plan was an orthopedic center, united to the general hospital only from an administrative point of view. This was an economic advantage; the services of specialists in various branches could be interchanged, without any interference in the actual orthopedic work. It was necessary for the orthopedic center to take charge of many chronic cases, and many adjuncts would have to be called in, such as electrotherapy, the gymnasium, and the curative workshop which could be connected with the center in colony form. The work shops necessarily had to be very elaborate and complicated and it would be impossible to have these in a general hospital.

Major S. C. BALDWIN, M.R.C., did not agree that it was a good plan to have the work of the orthopedic hospital in connection of that of the general hospital, as the orthopedic man would then be an assistant to the general surgeon and his special value would be lost.

Lt. Colonel STARR in concluding said it would be a great disaster in this country to use the orthopedic hospital as a subsidiary to the general hospital. The plan to put the orthopedic hospital under the same administration as the general hospital had its advantages and disadvantages; the former being the chance to co-operate with members of the staff in other branches. There were also economic advantages. In Canada the units were large separate hospitals and the patient was under control of the orthopedic man, except for questions of discipline and administration, which the orthopedic surgeon was not concerned with.

The Special Training Battalion of the Twenty-sixth Division.—Captain Z. B. ADAMS, M.R.C., said this battalion was established in March, 1917, with the object of the reclamation of as many men as possible by means of special training. Many serious physical defects were remedied and the men put into such physical condition that they could perform some service behind the line. It was found that 86 per cent. of the cases could be thus improved; 14 per cent. showed defects that entirely unfitted them for military service. The cases were divided into four groups with regard to seriousness of the defect. The classifications were: (1) men with faulty posture and slight pronation; (2) men with metatarsalgia; (3) men with acute strain or contracted tendons, faulty posture, and back strain; (4) serious defects requiring operation. The camp was in no sense a rest camp. All work was done out of doors and was of a military nature. The men were gradually advanced through five companies and the fifth company did really hard work. Three hundred and seventy-three men had been under training and in six weeks the battalion had been able to return 88 men as fit to carry on military duty and not likely to break down.

The Value of Casual Detachment as Tested at Camp Cody.—Captain E. R. RICH, M.R.C., read this paper. He said that the tendency was now to turn from hospital treatment to camp training. At first the man with flat feet was turned over to the hospital and he was apt to pass the good word along to his companions, so that the hospitals were filled with men with flat feet. It was found necessary therefore to deal with these cases outside of the hospital. Since the establishment of the first Casual Detachment work in Mexico, 8 out of 11 camps had followed suit. Such names as the "soldiers' salvage school" and the "orthopedic-back-to-duty class" had been bestowed on this work. The object of the work was to build up weak structures which were the cause of static foot defects. It was found better to have a line officer to maintain discipline; he could do this better than the medical officer. To give the best result, the soldiers must be segregated. Military habits were not relaxed so that the men might be impressed with the reality of war.

Major W. C. PETERS, M.R.C., said he had not had experience of men returning from the war. He had supervision of camps in the Middle West and he wished to speak of fundamental principles involved. Major

Hornsby had said that he did not consider this a time for the rehabilitation of the defective individual. Still, it was found that many cardiac cases could be treated by suitable exercise and many tuberculous cases could be made more fit. Even granting that operation was undesirable, many men could be made fit for the line, many more for limited service, and then there was the important point of equal justice. It was not fair that one boy should give up his position to go to France and get shot while the other boy should stay with his family and friends and keep his position just because he had flat feet. In the Middle West intensive training was used more than operative methods and the end was found to justify the efforts.

Major EMIL GEIST, M.R.C., said he was not a camp orthopedist, he was connected with the general hospital, and these problems were rather different. He had watched the work of Major Corbusier and it seemed to him that if one eliminated men from the army because they had flat feet they were going to waste a lot of good men, who at least were fit for selected service.

Captain MARSHALL, M.R.C., said that there were several very commendable features in this work of Captain Rich. In experience gathered as camp orthopedist at Camp Taylor he felt that many difficulties could be overcome by co-operation with hospital management. It was a big mistake to put a premium on disability. Many a malingerer would go from one ward to another and be seen by different consultants. A rank malingerer would thus pass his time surrounded by all the comforts of the Red Cross and it was impossible to play the detective continually. This occurred frequently and it was only by segregating these men that the plan could be worked out. Simulation of ankylosis of the knee was a favorite plan and these men would put in several months in the hospital. The plan advocated by Captain Rich was by no means a pleasure cure and was highly commendable in these malingering cases.

Captain TRUEHART, M.R.C., of Camp Cody said he had seen a whole camp suffering from psychic flat foot. The cure was made extremely strenuous and it entirely eliminated the psychic side. The real flat feet were left. The strenuous training was then let up and it was found that many of these men would never be really fit for military duty. Many of them made excellent bakers, but they could never march. Old empyema cases were put under a course of exercise to prevent scolioses which often developed after empyema. In this way one could clean out four or five hundred men from the hospital, and leave only 50 or 60.

Captain WHITBECK, M.R.C., said that he believed that this provisional regime was of the utmost importance. In the beginning of the war enlisted men were rejected for foot conditions which did not come up to the regular army standards. But it would be found impossible to preserve the standard of perfect feet. The second draft had picked up a lot of men who were passed by on the first draft and eight months had thus been lost. therefore it was of the utmost importance that good judgment should be used. If the men were examined in camp and referred to the casual detachment, the class could be placed under a supervision of an orthopedic man and many cases could be made fit by graduated exercises.

Dr. S. TWINCH of Newark said he would like to ask the members for some instruction in the examination of foot cases. The ideas were not uniform on the subject. One man rejected a foot that could not go into an ordinary shoe. Dr. Twinch said that many cases besides this were not fit and he rejected them, irrespective of the orders.

Captain TEST, M.R.C., of Camp Dodge, said the use of plaster would make no difference to the psychic foot, but with the really sensitive foot considerable relief could be gained by immobilization in plaster. Flat feet were of two kinds, the static flat foot, and the arthritic flat foot with history of rheumatism. There was little to do for the latter kind, the *x*-ray showing lipping of the edges of the tarsal bones. The static flat foot with stretched ligaments should be put up in plaster for four weeks to allow of subsidence of inflammation, and then it could be strengthened by exercise. Probably there were many perfectly good flat feet. There was strain observed with high arch also. The Scandinavian showed a thin foot with a high arch. This type of foot did not stand marching well. Putting pads under the matatarsal heads helped somewhat and increasing the size of the shoes helped more.

Captain RICH, in conclusion, said that he thought that any case bad enough to be put in plaster of Paris ought to be discharged. It was found difficult to get the casual detachment started in camps. The orthopedic man had to get in touch with the line officer and sometimes it was necessary to telegraph to the Surgeon General's office.

Organization of Division of Orthopedic Surgery in U. S. Army with Expeditionary Force.—Major JOEL E. GOLDTHWAITE sent this paper. Briefly stated the points covered were as follows: The chief work of the orthopedic surgeon is the salvage of men for duty; this consists of two parts: (*a*) proper physical training; (*b*) restoration of wounded. Under the first heading falls the general postural care, inspection of shoes and clothing, and special supervision of training. The second part involves the treatment or assistance in treatment of cases in which the bones and joints are injured, or in which the muscles, tendons, or ligaments which are involved in the control of these parts are damaged; it includes also proper supervision of splints and transportation.

Orthopedic Surgery in the Zone of Advance.—Major KENDALL EMERSON, M.R.C., presented this paper. In organizing an orthopedic unit, he said, the work was under a line officer and four orthopedic surgeons. It included two parts: First, under proper physical training men were trained to become fit for full combat duty; 80 per cent. of the men were enabled to reach this standard. The second part of the work dealt with the restoration of the wounded and included the splints used for their transportation and their subsequent hospital treatment and reeducation. It was felt that the orthopedic surgeon had a special duty to perform in the advanced areas of warfare. A stationary hospital with a permanent staff, five miles back from the line of battle, and equipped with 500-1000 beds could cover a great deal of active work. Different small staff units could be detached from this and be detailed to other points where the staff was overworked. Such small teams were mobile and could be added to or taken away from a unit. They should be equipped to do all kinds of surgery. A permanent orthopedic unit with detachable teams could be created under the supervision of a first-class orthopedic surgeon. A general surgeon could act as assistant and anesthetist. The orthopedic surgeon should be broad enough in spirit and ability to assist the general surgeon, when necessary in chest and abdominal cases. In fractures and joint injuries the trained judgment of the orthopedic man was necessary in the first instance.

Demonstration of Splints Applied.—Captain W. J. TAYLOR, M.R.C., made this demonstration. Appliances for the upper limb were shown—the elbow metal splint, the triangular bandage, the Thomas traction arm band. The more simple the apparatus was the better it worked at the battle line. The forefoot splint and the Jones long leg splint were shown. In injuries of the tibia it was found of more comfort to the patient to leave a side splint and a posterior splint together in use. A pad was placed under the Achilles tendon to support the foot.

The Treatment of Chronic Osteomyelitis Due to Gunshot Injuries.—Captain C. F. EIKENBARY, M.R.C., presented this subject. It was stated that sequestra might be left and thus persistent sinuses be formed which would remain for years and finally result in amputation. From a five months' experience at Ballahouston Hospital in Glasgow the author concluded that palliative operations in chronic osteomyelitis were of no avail. Treatment followed the lines of making a radical incision including as much of the sinus as possible. Sequestra were removed, together with much healthy bone, an inch above and below the diseased area. The chisel was slanted to leave a smooth-edged, shallow trough of healthy bone. This was packed with dry gauze, the skin being held by one suture at either end. The aim of the operation in such cases was (1) to get rid of all necrotic bone; (2) to avoid leaving any cavity at all; (3) to avoid leaving spicules,

rough areas, etc. Postoperative improvement was marked, healing taking place within four weeks.

Primary and Delayed Primary Suture in the Treatment of War Fractures.—Major WILLIAM S. BAER, M.R.C., A.E.F., presented this paper. American surgeons, he said, had arrived on the scene when the principles of general war surgery had been established. Since August, 1914, wonderful strides had been taken from the old painful prolonged treatments to the present methods with the almost complete restoration of function. These hard and costly lessons had been learned by our Allies. The principles of war surgery so far established were: (1) all wounds were to be considered infected; (2) it was necessary to remove all projectiles, clothing, and devitalized tissue if possible before the 12th hour after the injury; (3) when removed within this period such wounds could be considered aseptic in character and a primary suture made, thus converting compound fractures into simple fractures. In skilful hands primary suture could be performed (before the 12th hour) in 80 to 95 per cent. of the cases. When primary suture was not found possible, the socalled secondary suture, in which the wounds were closed on the second, third, or fourth day, would be found successful in 80 to 87 per cent. of the cases.

The Pathology of the Peripheral Nerves in Gunshot Wounds.—Captain SYDNEY M. CONE, M.R.C., presented a report which included observations upon two hundred cases of nerve injuries, both severed nerves and those involved in scar tissue. It dealt with the pathology of degenerating nerves and stated that proliferation took place at both proximal and distal ends and that bulbous terminations of severed nerves were composed chiefly of actively growing nerve tendrils and comparatively little inactive tissue.

Orthopedic Treatment of Nerve Lesions.—Major WILLIAM G. ERVING, M.R.C., presented this paper. The problems of this subject he said were numerous and complicated. Each step was important and the treatment might be divided into three groups (*a*) supporting and protecting, (*b*) operative, (c) non-operative. In connection with the first it was found necessary to have splints to overcome the defects produced by sensory nerve lesions, such as wrist-drop. To prevent stretching of muscles a light papiermaché model was used, and various other appliances were used to prevent contractions or malpositions of hand or foot. The manipulation of adjacent joints was necessary to prevent deformity. The operative treatment consisted of (1) freeing muscles and tendons from scar tissue; (2) freeing nerves from scar tissue; (3) suture of divided nerves; (4) tendon transplantation; (5) arthrodesis. Non-operative treatment consisted of faradic stimulation, diathermy, hydrotherapy, massage, passive and active exercises, workshop training, and mechanotherapy. The mind had to be trained to help to train the muscles. The proper sequence and coordination of these methods required the supervision of the patient by one surgeon throughout, who would take into consideration all the problems involved and give to each step of the treatment its proper place in the general scheme.

Operative Technique in Contracture of the Hand.—Major ALLEN B. KANAVEL, M.R.C., gave a lantern demonstration. In injuries of the median nerve, he said, the annular ligament was an important structure. Injury to the ligament caused necrosis of the nerve. Increase of anemia in the parts hastened nerve destruction. In studying the relation of the nerves to the wrist joint, where the os magnum, the unciforme, and the trapezium were destroyed, the removal of the distal row of bones was not sufficient. Care should be taken not to mistake the fibers of the median nerve for the tendon. Great help could be obtained by following the nerve fibrils with a magnifying glass. A picture of the hand of a pianist was shown, in which restoration of function was complete after injury. Continuity of the nerve was restored, the nerve wrapped with a pad of fat, and the tendon sutured with silk.

Reeducation in the Functional Disabilities of Actual War Service.—Captain WILLIAM W. PLUMMER, M.R.C., presented this paper, which was the result of experience in the 2nd National general hospital under Dr. W. C. Morton of Leeds, England. Before reeducation the history and conditions were carefully analyzed. The patient was convinced by demonstration that the wound was not responsible for the symptoms. The degree of functional disability was noted. Treatment was made to include passive and active exercise, faradism, and voluntary efforts on the part of the patient. The patient was allowed to feel his troubles were real and that no stigma was attached. The patients were not segregated and the general tone was good and spirits high. The reeducation was given in private until the patient acquired confidence and the idea of what his muscles should do was always held before him.

A System of Orthopedic Instruction.—Major R. W. LOVETT, M.R.C., made this presentation. Experience had shown that in the intensive training of military surgeons, teaching to be effective must be more fundamental. The work was seen from a new angle and consisted of graduate instruction pure and simple. In the present war the mistakes of the surgeon would not be shown on examination paper, but his failures would be demonstrated on the soldiers in camp, therefore the training of the camp orthopedic surgeon must be fundamentally thorough. It was of no use to talk about a tuberculous joint to a man who did not understand what a joint was. The study of the normal joint must be undertaken before the study of joint disorder. The vulnerability of the joint and its reactions to trauma and irritants should be taught. All subjects allied to orthopedic surgery should be covered and the instruction should be as largely clinical as possible. Points of instruction should be (1) diseases of the neuromuscular mechanism; (2) passage of the nervous impulse from the cortex down; (3) lesions in the synapse, in the brain cortex, after leaving the cortex; (4) muscular lesions and disturbances of motor function explained; (5) explanation of lesions in weakened muscles and the relation of flexors and extensors (the former being stronger than the latter and more apt to cause deformity) being demonstrated; inhibition, due to cerebral lesions is analyzed; (6) peripheral nerve lesions studied; thus covering all points of the neuromuscular mechanism. The second part of the course would deal with static deformities and the causes of muscular depreciation, foot strain, scolioses, etc., would be considered. This study would include mechanical peculiarities of the different joints and results of taxic invasion of joints. Here would be considered the indications for operation on general pathological and functional grounds. Tuberculosis, arthritis, and syphilis would be considered in this connection. Growth of and function of bones and bone lesions would next be dealt with. The last part of the course should cover the question of apparatus and artificial appliances, the reasons for application of apparatus and the suitability of plaster, iron, or leather being shown. Under this subject would be included (1) fixation; (2) traction; (3) support; (4) correction of deformities. Students would work out for themselves the mechanical need of the apparatus. Dr. Lovett said that the students responded extremely well to such an intensive course. The whole aim of the work was to use education in its real meaning, that is "drawing out" instead of "putting in."

The Camp Greenleaf School of Clinical Orthopedic Surgery.—Major EMIL S. GEIST, M.R.C., made this report. At present it was stated that 1000 doctors were in course of training at Camp Greenleaf. A course of four weeks was spent in intensive training in subjects necessary for every medical military man. This included drill, physical training, military hygiene, and orthopedic surgery. The chief points aimed at are (1) making the army fit for service; (2) keeping it fit. The camp was near a large hospital where clinical material was easily accessible and the patients were soldiers. Osler had said that "if a man understands typhoid well he has the foundation for internal medicine" and it could also be said that if a man understands a tuberculous joint he has the foundation for orthopedic surgery. The main point was to avoid deformity and the treatment of the tuberculous joint lent itself to this study. An outline of the day's studies at the camp was given: drill 7.30 to 9 a. m.; the men began school at nine. Courses included anatomy, neurological and pathological; *x*-ray diagnosis; nerve surgery; history taking and recording; a special course

on foot ailments, as applied to the soldier was given. The importance of the latter could not be overestimated. There was also a literature course and the students were encouraged to abstract and discuss the best available literature on military orthopedic surgery. One important item of the training was the making of models of braces and apparatus, the simpler the better, and a great deal was done with simple wire models which the graduate was able to carry about with him so as to be ready to apply the instruction in the first emergency.

The Moving Picture as a Method of Teaching, with Special Reference to Post-Graduate Work.—Major R. T. TAYLOR gave this presentation. The great need of illustration in post graduate instruction having been felt, the Surgeon General's Office had undertaken to equip a Medical Art Department of the Army Medical Museum. This would furnish a postgraduate research library of the highest value and the work of the Government should be enthusiastically supported by the profession in order to make this work a treasury for all specialties. The Government had to meet great demands, coming from all the camps, for moving picture illustration. Colonel Owen was at the head of this work and he had undertaken to supply the illustration of such subjects as war neuroses; tendon and muscular transplantation; intestinal anastomoses; application of deep sutures, etc. These subjects were brought home to the student and fixed in the memory better by illustration than by any other means. In combination with suitable lectures this teaching gave a higher average for the students than any other method.

The Problem of the Chronic Disabilities of the Soldier.—Captain FRED J. FASSETT, M.R.C., A.E.F., presented this paper. It was stated that the chief hindrance to successful orthopedic surgery was found in sepsis. The time for treatment of compound fractures was therefore before infection had set in; if not, modern orthopedic methods could do nothing in the way of restoration of function. In the military hospital the surgeon had to encounter a certain attitude of resistance among the patients. The men wanted nothing better than to be let alone. This inertia was a psychic factor difficult to explain, but necessary to combat. It was the reaction after two or three years of abnormal trench life and the wounded man had lost connection with the military side and had not yet reestablished it with civilian life and duties. Mental readjustment would take time, and the men do little to help themselves. The inspiration must come from the doctors and nurses. Prolonged hospitalization was found to have a depressing moral effect and a man unfit to return to military life should be at once put in relation with the outside world, and helped to find his new industrial station. An Out-Patient Annex Department could bridge over the gap and care for these patients in their new start in life. Without this help at the difficult point of readjustment the returned soldier was apt to remain a moral as well as a physical cripple.

Some Aspects of the Military Massage Problem.—Miss MARGUERITE SANDERSON, read this paper by invitation. This problem the author said was not so much a technical one as it was a question of administration. The types of cases to be treated were largely comparable to injuries in civil life, but the treatment was necessarily more intensive. A knowledge of anatomy was imperative and an individual study of each case was necessary as the same lesion in two different patients could not always be treated alike. The patient's cure might be said to depend to a great measure on the moral force of the masseur or masseuse. Women of thorough and special training and with education and intelligence were needed for the work. The massage was coincident with reeducation and a knowledge of anatomy, physiology, and medical gymnastics was essential. The support of othopedic surgeons was necessary to give the proper status to the kind of women needed for the work in the military hospitals. To keep the standard of the work high the position should be made dignified and responsible and proper compensation be allotted. This would be brought about by the influence and cooperation of the orthopedic men.

Electrotherapy and Hydrotherapy.—Lt. Colonel R. WILSON, R.A.M.C., Ottawa, Canada, said he would devote the time allotted to speaking of his experience in England and France. The American Medical Reserve Corps seemed to be groping for information of all kinds which had a practical bearing on military questions. Therefore, though his remarks might be somewhat rambling, he hoped that some of the things they might gather would be helpful. Electro- and hydrotherapy were only two of the many methods used in the cure of wounded and disabled soldiers. In regard to hydrotherapy,—in England there had been installed what were called "au courant baths"; that is, those in which the water was kept continually in motion by means of nozzles of compressed air. This was similar to the "Whirlpool bath" in which two nozzles forced the water in opposite directions. In the still bath there was always a layer of cooler water forming next the body and the whirlpool bath did nothing more than keep an even temperature round the limb. The addition of compressed air to the bath was supposed to keep up a certain definite massage of the limb by the pressure of air bubbles, but the speaker said he was not convinced that the results claimed, justified the extra expense of this apparatus. Where water was scarce, however, it was cheaper than a continual flow of running water. In addition to hydrotherapy massage was given and this was thorough and specific in regard to the patient's disability. The treatment by the au courant bath cut down the time necessary for massage by one half, by relaxation of the muscles and loosening of the lymphatic circulation. When one came to the question of electrotherapy, one was upon debatable ground. There was great dispute among the authorities as to what effect electricity had upon the tissues. The effect was not really known. Col. Wilson said it was his custom to give a continuous current from above down for half the time and then to stimulate the muscle by other means for half the time. A common mistake was to suppose that a muscle severed from its nerve would respond to Faradic stimulation. This was impossible. The properties of electricity were the same, no matter where obtained, whether 3000 volts or 20,000 volts, whether it went backwards or forward, up or down, the important point was the effect upon muscle tissue; the severed muscle tissue could not respond. For treatment of a paralyzed muscle, in conjunction with massage, the galvanic current was used. It must be remembered that the weak muscle would not do as much as the strong muscle and that nothing should be done to suddenly jerk the weak muscle. One could not insult a damaged muscle.

Bedside Occupational Therapy as Proposed for the Military Hospitals.—Major HENRY R. HAYES, M. R. C., said this was by no means a new procedure. The experience of civil life was being applied to military hospitals. In the Walter Reed Hospital, Washington, D. C., the principles of occupational therapy were being tried out. Hitherto, the army had been solely concerned with the return of the soldier to active duty, but there were many who would only be fit for restricted duty and some for civil life. Ward occupations were instituted for those patients still in bed and in chairs, and was to be considered as pre-vocational, intended to stimulate the patient to return to regular work later. One essential of the treatment was that the work should be continuous. It was of the greatest consequence that the work should not flag or lapse owing to lack of material. Such occupations as weaving rug and mat making, wood carving, basketry, and bead work could be well handled by patients. The work should be simple, easily finished and have commercial value. This would afford the patients training in concentration and coordination.

Foot Problems and Treatment with Unseasoned Troops.—Captain CLARENCE B. FRANCISCO, M.R.C., presented this paper. One of the first difficulties he said was to secure shoes large enough to meet new demands. The ordinary man in civil life walked little and the muscular development of the foot was prevented. A No. 9 foot usually tried to wear a No. 7 shoe. The strain of marching with the addition of the heavy pack on the back necessitated wearing of a shoe two sizes larger than in civil life. Trench foot had now come to be considered a preventable disease.

The Thomas heel and the French marching strap had proved very useful in prevention of foot strain. The ordinary commercial arch support should be legislated out of the market. Men with marked deformities of the foot, such as hallux valgus, hammer toe, rigidity, and flat foot should not be sent abroad. Such cases were sure to break down under the unusual strain and to take up space in hospital needed for more sick patients.

Foot Prophylaxis in the Soldier.—Major J. T. RUGH, M.R.C., in this paper dealt with the recognition of the potentially weak foot and its restoration to full strength and efficiency. This might sound in theory an easy matter, but its practical application was very different in the service. The problem might be divided into four headings: (1) feet; (2) shoes; (3) officers; (4) soldiers. Emphasis was laid upon the necessity of instruction to the officers in order that they might be able to detect in time the potentially weak feet. In the examination of 50,000 soldiers 27.5 per cent were found to have functionally weak feet. In regard to the shoes, need of proper care in drying the shoe when wet was pointed out. The sock should be worn inside out, or with the smooth side next the foot, on a long march. Oiling the shoe would prevent its becoming stiff and hard. The Munson type of shoe would be found to fit 98 per cent of the men satisfactorily and would save eight out of ten foot inefficients. The foot of the young soldier up to 25 years of age was very adaptable, but after that it became less elastic. Factors of weakness were: short heel tendons hypertrophied scaphoid, supernumerary tarsus, congenital valgus, bad shoes, improper posture, muscle weakness, overwork. The chief prophylactic measures employed were: (1) detection of weak cases; (2) proper alteration of shoes; (3) instruction as to walking; (4) exercises; (5) protection from strain.

The Orthopedic Service at Fort Riley.—Major J. T. LORD, M.R.C., read this paper. When the examining boards began their work it was a matter of surprise that there were so many potential cripples. Among 5000 men 76 per cent were found with foot inefficiency in some form. A number of malingerers were always to be found and there was a certain psychology behind this (often very persistent sham) that needed special measures to deal with it. In regard to foot disabilities, there were an extraordinary number of cases of the following: over-and under-riding toes, exostosis of os calcis, of internal cuneiform and of first and fifth metatarsals. Other disabilities noted were abnormalities in hip-joint or knee-joint, disturbances due to excessive drill, arthritides and mouth infections, primary minor ailments, plus the psychoses, metastatic joint infections.

(*To be concluded.*)

Nasal Leprosy.—According to Leñon, the frequency and early appearance of lesions in the nose give rise to the belief that the inoculation occurs at that region with especial preponderance. The appearance of crusts in the nares with an ozenous odor is often accompanied by nosebleed—indeed nosebleed as a forerunner of leprosy has in certain localities where the disease prevails almost as much significance as hemoptysis as a forerunner of pulmonary tuberculosis. When the first eruptions manifest themselves there is an aggravation of the intranasal symptoms. The chancre-like lesion in the nostrils may be followed by the development of leprous nodules in the alæ nasi. The skin here is also analgesic. The leprous manifestations in the nose have to be differentiated from several conditions, as syphilis, tuberculosis, and ozena. In both ozena and nasal leprosy there are fetor, crusts, and hemorrhage. The parallelism here is so close that a diagnosis must be made by collateral symptoms unless open ulceration is in evidence (this excludes ozena). The presence of anesthesia of the nose readily makes the diagnosis. In old cases there should be no confusion, for the atrophy produced by ozena has of course no counterpart in leprosy and with the development of the disease other symptoms of the latter are in evidence. Diagnosis between leprosy on the one hand and syphilis and tubercle on the other can be facilitated by bacteriological and serological tests.—*El Siglo Médico.*

Miscellany.

Effects of the War as Shown by Vital Statistics.—Sir Bernard Mallet, in a lecture delivered at the Royal Institute of Public Health recently and published in the *British Journal of State Medicine* for August, 1918, referring to the decline in births occasioned by the war, says that the loss in potential lives in the United Kingdom represents 1.63 per cent. of its total pre-war population. Serious as is this loss to the coming generations in Great Britain, there is reason to believe that the other belligerent nations have suffered more. In terms of percentage of loss it may be assumed that Germany has lost in potential lives the equivalent of 4.5 per cent. of its total pre-war population, Austria over 5 per cent., and Hungary 7 per cent. For France it is more difficult to form any estimates, as the reliable material at disposal is small, but it is probably over 3 per cent. For Russia, Italy, Belgium, and the Balkan States Mallet is not in a position to attempt any detailed estimate of loss in potential lives. He thinks, however, he may safely hazard the statement that in its first four years the present world war, by the fall in births which it has occasioned, has cost the belligerent countries of Europe no less, and probably very many more than twelve millions of potential lives.

It will be seen, then, that the negative results of the war on human life have been as far-reaching as the positive, that the loss of the populations of Europe is probably no less serious from the decline in births than it has been from the deaths on the battlefield. At the present time every day that the war continues means the loss of 7,000 potential lives in Great Britain, France, Italy, and the Central Empires. These figures are appalling, but it is probable that they fall short of the actuality.

The losses, however, are not confined to belligerents. It is stated in the "Annuaire International de Statistique "that the neutral countries of Europe have also suffered a decline in varying degree in the number of births recorded. For 1915 the births in Switzerland show the remarkable decline of 16 per cent. on the average of the preceding triennium, a decline considerably in excess of that shown in the United Kingdom and more than two-thirds of that in Germany. This decline is naturally due in great measure to the exodus of foreigners from Switzerland after the outbreak of the war, but probably it is attributable to a very much greater extent to the mobilization of so large a proportion of Switzerland's citizen army.

In 1915-16 Sweden shows a decline of 7 per cent. on the average of 1912-14, Norway one of 5 per cent. for 1915, Denmark 4 per cent. for 1915, the Netherlands 2 per cent. for 1915-16, and Spain 2 per cent. for 1915. The smallness of the fall in the Netherlands may to some extent be explained by the presence there of some hundreds of thousands of Belgian refugees. Taken together these three Scandinavian and the two other neutral countries show a loss, for the year 1915 only, of nearly 50,000 potential lives through the fall in the numbers of births.

A NEW OPERATION FOR HALLUX VALGUS.

BY LT. COL. J. TORRANCE RUGH, M.C., U.S.A.,
OFFICE OF THE SURGEON GENERAL, U. S. ARMY.

THE surgical treatment of hallux valgus has been rather extensively considered by many different writers and the various procedures advocated have each some points of advantage and also some points of disadvantage. The ideal type of operation is that which corrects the deformity, removes the exostosis from the lower end of the metatarsal and yet preserves the normal functions of the joint with the function of weight-bearing beneath the great-toe joint. If the osseous hypertrophy is not excessive and the deviation of the great toe not over 30°, exposure of the joint by a curved logitudinal incision and removal of the exostosis from

FIG. 1.

FIG. 2.

the inner side of the lower end of the bone (Fig. 1) will prove all that is necessary, though care must be had to leave no sharp edges or points on the bone as these will cause trouble later through pressure of the shoe on them. No interference with the function of the joint and no loss of the weight-bearing surface underneath the metatarsal will occur here and the results are satisfactory.

If there is more than 30° eversion of the great toe or if there is marked hypertrophy of the lower end of the metatarsal, some more corrective procedure should be employed. First, the hypertrophied portion should be removed, and then one of two methods has usually been followed. A cuneiform osteotomy may be done back of the great toe joint and the toe brought over to a straight line and so held until union has become firm (Figs. 2 and 3). Or the posterior portion of the proximal phalanx of the great toe may be removed and the remainder of the toe set over to a straight line in front of the metatarsal (Fig. 4). Both of these methods preserve joint function and the support under the metatarsal head. Radical removal of the distal end of the metatarsal (as in the Mayo operation) brings disability in many cases and has not infrequently been followed by ankylosis.

FIG. 3.

Some one has said "what is new is not true and what is true is not new," and I hesitate as to claims of a new operation for this condition, but to the best of my knowledge the following method of operating has not yet been reported and so far

FIG. 4.

as I know it was first done by myself in the fall of 1916.

The joint is exposed by a curved, longitudinal incision (Fig. 5) and the flap (base down) is dissected free to the lower edge of the joint (Fig. 6).

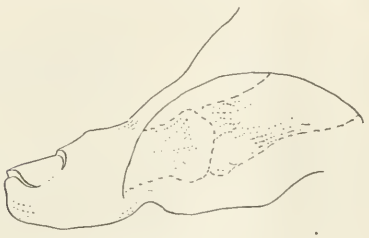

Fig. 5.

A tongue-shaped flap is then made (base backward as in the Mayo operation) and should include the bursa and the internal portion of the capsular ligament back of the base of the proximal phalanx of the great toe (Fig. 7). This is turned backward and the lower end of the metatarsal freed of ligamentous attachments. With a sharp osteotome or

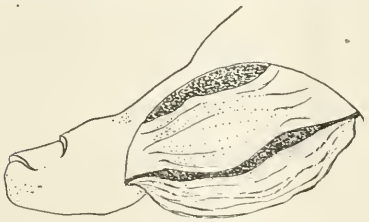

Fig. 6.

chisel, sufficient of the epiphysis of the metatarsal is then removed to allow straightening of the great toe. This usually amounts to about one-fourth inch. This cut also is made slightly diagonal from within outward and from behind forward (Fig. 8). The inner sharp and hypertrophied corner is next removed with the osteotome and if this instrument is properly sharpened a mallet is unnecessary, as

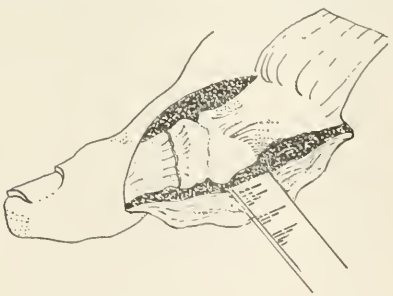

Fig. 7.

the edge can be pushed through the bone with the hand alone. The top and under parts of the epiphysis are then taken off to make a wedge-shaped end on the bone (Fig. 9). The slant on the top can be made very much greater than underneath so as to leave as much weight-bearing surface as possible. There will also remain the supporting surfaces of the sesamoid bones on the under surface of the joint. The tongue-shaped flap of Fig. 7 is then passed across the end of the bone,

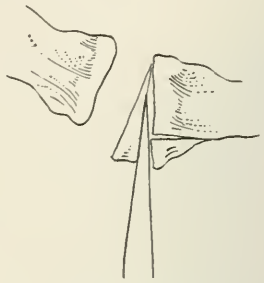

Fig. 8.—Top view.

covering in the wedge and secured with sutures if necessary. Sutures are then passed from the base of the tongue-shaped flap on the inner side to the base of the proximal phalanx, sewing back and forth to hold the toe toward the inner side. The skin incision is next closed and dressings applied to hold the toe inward. The bandage should make a figure-of-eight about the toe and foot and hold the toe horizontal and slightly adducted. In some

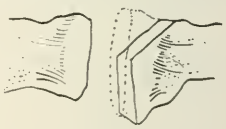

Fig. 9.—Lateral view.

cases a splint of wood or plaster may be advisable, but this is seldom necessary. After two weeks time the use of the foot is permitted and weight-bearing advised.

Ankylosis is practically impossible because of the hinge-joint which is secured, weight-bearing is preserved, and the deformity is removed. The operation is simple of performance and the results in twelve cases done thus far have been excellent.

BIOLOGICAL FACTORS OF THE WAR PSYCHONEUROSES AND COMPLEMENTARY PHENOMENA.

By HOMER WAKEFIELD, M.D.,

NEW YORK.

In a recent article on war shock,[1] we endeavored in a running commentary on some of the current literature on the subject to point out a few apparently neglected facts that seemed to have direct bearing on the live issues presented by the great war. It was, however, not until a monograph by Dr. Stewart Paton, entitled "Mobilizing the Brains of the Nation," was placed in our hands that we were brought to a full realization of the real demands of the occasion. This has led to the preparation of the present paper in an endeavor to supply as best we can the higher standard of biologic analysis and elucidation called for by Dr. Paton.

Did space permit we would like to quote his entire article, but we will suffice with the following as expressing the present situation and its demands upon Americans collectively to meet: "We cannot without sacrificing conditions essential for the preservation of personal and national sanity hide the fact that many of the attempts made to face the actual issues of life are at the best half-hearted efforts; while the recognition of critical situations or events is interfered with by the tendency to compensate for defects in perception by introducing a vague mysticism. . . We need to go to the root of the trouble and get accurate information as to the structure and function of the machine we are trying to operate. How do we expect to control temperament and character if we are ignorant or indifferent in regard to the nature of the biological mechanisms regulating temperament and character? . . It requires both courage and intelligence to face the fact that comparatively little is known of the laws governing human behavior, but when once the admission is made, then it is our first duty to accept the privilege of working hard to add as rapidly as possible to the present stock of information. . . The present catastrophe which threatens civilization is one of the tragic results of attempting to organize society in order to satisfy theoretical conceptions without taking cognizance of the fundamental laws that govern human nature. If we had been familiar with the biologic mechanisms controlling the personality, we might have been alive to the danger lurking in any conception of duty which carries with it the idea of 'special dispensation of Providence,' or missions to reform for which others are unfitted. . . Man has been so absorbed in trying to discuss life in abstract terms that he actually forgot to inform himself even as to the principal events taking place in the life of any one person in the effort to adjust successfully to meet the daily needs. . . Eventually, as the result of insisting upon the value of biologic methods in the analysis of all forms of social, national or racial activities, we should be less inclined to promise permanent peace until something more is known of the actual conditions regulating the genesis of motives and impulses or limiting the sphere of voluntary control of actions."

The specific endeavor of the present paper is an elucidation of effects exhibited in the war neuroses, and especially to bring those elements usually classed within the domain of the *psychical*, as well as the neurological into an unbroken contiguity with the well-known phases of the *physical, biological* and *physiological* sciences. So long as ignorance or a vague perspective bedims the view, the clinical picture of all the war neuroses, including shell shock, and their interrelations will be obscured and the nature of the causative factors will be misinterpreted. So long as any human maladies are pronounced *psychical*, and as such metaphysical or non-physical, their pathology will be enveloped in vagaries, their therapy will languish for sustenance and victims of their derangements will become delinquents and public charges through neglect of proper treatment.

There is nothing mental which is not also physical. There is no *psychical* which is not the *physical* product of the somatic physical body. Sensation, the muscular sense, and all the five special senses are more or less highly specialized and complete organic functions which narrow the range of characters of the stimuli, to which they are reactions, as response phenomena of the inherent irritability, that vital character, more than any other, by virtue of which the primitive unicellular organism lives and has its being, as completely traceable by man. This property, irritability, we shall trace in its many elaborations in the phases now before us.

Even emotion, which is by some writers, of all human manifestations held most supernatural, is most closely connected and allied to *physical* phenomena in general, and is *per se* the most clearly expressed as motor phenomena and by contractile phenomena of muscular and other less contractile tissues. As we have seen, the more violent and depressive emotions or paroxysms of the emotional allied phenomena, are spasmodic contractions or contractile constrictions which often deflect the major volume of the blood from the superficial to the deep (splanchnic venous) circulation.

The nomenclature of the subject is so vague and ill-defined that demarcation lines are difficult to draw, and moreover identities and definitions are especially unsatisfactory in addressing a paper to an unprepared reader. Emotion, now brought down to a physical basis, is yet more difficult to differentiate from hysteria, while the lesser emotions would not be characterized as hysterical. Hysterical paroxysms, short of epileptoid convulsions, are usually termed emotional and the question arises: where comes the line of demarcation between the superficial spasm of the emotional and the somatic tonic and succeeding clonic contractions of hysterical convulsions, and where is the line that marks the point of division between the epileptoid and the true epilepsy which it not infrequently develops into when successive repetitions as hysterical manifestations are not curbed in time to circumvent the operation of the law of repetition which provides that all physical actions are facilitated by previous actions of the same tenor, and are further facilitated corresponding to multiplicity of antecedent ones.

Repetition of emotions foster chronic emotionalism, and furthermore correspondingly lower the level of overflow, thus diminishing the height of attained head necessary to obtain vent through the safety valve emission of cumulated physical motive force. In fact an individual may become so emotionalized and so emotionally weak that every trivial factor may produce an emotive emission.

Emotions of apparently diverse types are atypical apart from emotionalism, *per se*. For example religious emotions serve as well as any to promote an emotionalism which may be reexhibited as sexual emotion, dipsomania, or a paroxysm of fear or other form of neurosis at the battle front. On the other hand hetero-and homo-sexual excesses and vices or alcoholic addictions become productive of the chronic emotionalism, the effect of which, in general, is to lower the resistance, permitting emission at progressively lower and lower levels.

The medical problem is not only one of prevention of emotionalizing of men in training for the army and in the trenches but also of the returning war neurotics who are distinctly injured by any type of emotion, either profound, violent, depressive, or re-

peated. Emotion is in essence a spasmodic response phenomenon and its cultivation is an invitation to other expressions of the spasmodic dyscrasia. Spasmodic reactions become habitual.

Oppenheim[24] has recognized the importance of the vasomotor-wrought disturbances, but suggests that the painful neuritic symptoms point to a hypothetical wave of molecular changes in various parts of the nervous system as an impact resultant. This, however, has been rejected by several authors. He does not attempt to explain how such an effect on the nervous system would cause the observed vasomotor phenomena or how the terrific neuritic pains are benefited by hot baths, superheated air, etc., which he employs.

The Tissue Density Factor.—All writers on emotionalism, hysteria, spasmodic manifestations, convulsions, shock, etc., as psycho-neurotic phenomena, recognize a common predisposing cause vaguely termed constitutional inferiority, congenital defect, neurotic constitution, the stigma of heredity, degeneration, defective development, etc. The question at once arises: what is the nature of this vague something of such prime importance, which, coming as accidents of constitution, of heredity, of birth and of development, is responsible for such a multiplicity of syndromes? It does not bear out anatomical conformity to the nervous system so there is no use in abstruse speculations as to the part played by the neurones, by the central nervous, or the sympathetic systems.

It is obvious that this predisposing cause is some specific unit physical condition which is in turn responsible for a typical action and effect which shall be compatible with those exhibited as prime etiological factors and consistent with the superimposed factors exhibited as ultimate exciting causes of the group of ultimate manifestations under consideration. This specific *physical* condition must be an actual one, confirmatory by proper investigations. Its alleged typical action must be subject to substantiation by recognized methods of observation, and so on through to the last analysis. Such a series of tests can be wholly satisfied only by the *tissue density factor*, and by the relation of tissue density to response phenomena.

Regardless of what angle we approach the subject the results of investigation are never disappointing. Wherever we find living tissue, whether in man or the lower animals, the state of tissue esthesia corresponds with its state of density. In man, in all divisions of sex, age, race, health and disease, the tissue density corresponds with the exhibited sensibility attributes. In induced conditions the tissue density falls as deviations from the normal are induced. Development of growth is one from a lower to a higher density, and arrested development carries with it a correspondingly lower tissue density. All tissue reversions to or toward the embryonic form (atavism) revert to a correspondingly lower tissue density. Thus atavism has come to be recognized as a cause of stigmatic phenomena.

Sunstroke, so called, or more properly heat-stroke, is a typical example of reduction of tissue density by heat, often in persons previously free from neuroses in which are thus produced hyperesthesia and the several stigmata of the hysteric and the neurotic. Americans resident in the Philippines experience increasing hyperesthesia which becomes so great by the third year that they must leave the tropics or suffer irreparable deterioration. High surface heat in its effects on peripheral tissue density and in its production of hyperesthesia of the superficial tissues is thus productive of supersusceptibility to cold and to spasmodic reactions to chill attended by the characteristic overt recoils of the susceptibility wrought in neuropathogenics. Continuous hot baths also have the unfortunate ultimate effect of augmenting hyperesthesia—the prime factor of neurotic and other spasmodic affections.

The systematization of hysterical manifestations in accord with the common muscle associations of daily life functions, rather than of unit nerve distributions, evinces the influences of the law of reaction repetition, automatism and fatigue influences upon their esthesias which are inseparable from their sense memories which the psychical theorists admit as such an important factor.

The "jumpiness" of the war neurosis is caused by characteristic systemic tics which are typical of the sudden starts of fright from which they take form as habit or repetition phenomena. They may be characterized as memory manifestations. They are easiest cured by the earliest treatment, by the eradication of the underlying hyperesthesia.

The Physical Bases of the War Neuroses.—It must be obvious to all unprejudiced investigators that no unit pathological lesion can be broad enough to blanket the extremes of war hysteria on the one hand and war shock on the other. They have, however, some common factors. Depressing and intensive emotions, apart from concussions and shock, exhibit corresponding indications of spasmodic circulatory deflections, approximately evacuating the periphery and extremities and coincidently engorging and producing stasis of the major trunks, and lesser splanchnic veins. In cases of shock and collapse, this circulatory condition is more pronounced and approaches yet nearer the typical status of death. Both the hysterical and the shock cases thus have a *physical* basis, but only the latter may be said to exhibit organic damage. It is truly a paradox of pathophysiological nomenclature that the obvious superirritability (overt reaction) manifestations of the paranchymatous tissues are so universally dominated *nervous* phenomena and that just as obvious manifestations of *organic* damage to the nervous structures are so often dubbed *psychic* in nature. Such are the current interpretations of war hysteria and war shocks. True, there are also exhibited all gradations of transition between the above named extremes, and shocks frequently are engrafted upon hysterical foundations, resulting in all degrees of relative proportions of the two elements.

Strumpell gave us his concept of that vague sense of irritable weakness, of chronic perturbation, ferment and restlessness which goes by the misnomer *nervousness* when he wrote[25] "What is called nervousness, is, from a scientific point of view, above all a spiritual and not a corporeal disposition." Since science knows not the term *spiritual*, and has never attempted to analyze or define it, we must interpret his use of it as meaning *psychic*, in the non-corporeal sense. It is, however, significant as an admission by this great authority on the nervous system that while he is willing to relegate it to the domain of

mysticism, he nevertheless disowns it as of actual *nervous* origin.

Since we now propose to place the *psychical* within the range of the physical or corporeal we hope there will be no occasion in the future for the induction into scientific nomenclature of the word *spiritual*. We may then refer to mental and nonmental functions of the physical body without fear of confusion of interpretation.

Nervousness, so called, is the most common manifestation of somatic hyperesthesia. We referred in a former monograph[37.1] to Kennedy's paper entitled: "Nature of Nervousness in Soldiers". While usually associated with emotional instability, they should have distinctive differential interpretations in order to avoid confusion and misconception. Let us allude to the *hyperesthesia* of soldiers for the sake of a more universal and definite nomenclature.

If we differentiate the neuroses into sthenic and asthenic, we thereby provide a basis of identification and discrimination. Both are hyperesthetic states and both are characterized by weakness, but the former much less than the latter. In these the physical strength varies in as wide a range as that between the high grade moron and the feeble minded. The sthenic, the well nourished but sedentary and soft individual, attains the highest degree of tensional stress or excitement, culminating in the highest degree of explosive violence of outburst or overflow. He is the highest strung hysteric. Conversly the asthenic is the typical neurasthenic. Between these two extremes we have all gradations of transitional phases. All characterized by irritability and weakness. The sthenic type manifests its physical motive force in the explosive violence of its outbursts rather than by the enduring strength exhibited by sustained effort. On the other hand the asthenic phase is characterized by great weakness which permits no accruement of energy of kinetic value prior to its emission in the lowest form of sterile emotion. Perturbation produces exhaustion after imperceptible recoil responses. Both of these extremes and all intermediate states demand rehabilitation of tissue integrity, but the first may begin with graduated active exercises while the latter must begin with passive massage, manipulations and exercises cautiously interspersed with rest; the physical treatment never passing the fatigue limit, nor the rest-full recuperation. The work cure, however, is in general preferable to the rest cure.

Having already in a recent paper[37.1] discussed in considerable detail the fundamental biological reactions as aggravated by stigmatic hyperesthesia and the duplex common physical factor of spasmodic blood deflections from the superficial to the deep circulation, and from the peripheral capillaries to the splanchic venous reservoirs, resulting in serious venous stasic and circulatory disequilibrium, we will pass on to other complementary phenomena.

Hyperesthesia.—It is not with a view of merely correcting or improving the nomenclature that we are striving for the recognition of the physical basis of so-called purely psychic phenomena of the neuroses, but rather of the establishing of a sound basis of co-ordinated theory and treatment. At the outset both sides of this discussion admit that these socalled *neuroses* are not typically *nervous* functional irregularities. Charcot demonstrated the freedom of the nerves, cord, and brain from any related enduring lesion, in his famous lectures of 1884-5. Also stigmatically affected areas do not conform or correspond to those of nerve trunk distributions.[13]

Let us first review the objective of our own recent literature[37.1] setting forth that *hyperesthesia* is expressive of a tensional, a tetanic form of typical contractile reaction, resultant of low density of tissue, from any cause producing such a loss of tissue integrity, and that *anesthesia* is just as typical a resultant of tissue constricting spasms, of which hyperesthesia is the specific predisposing cause. However, purely psychic hyperesthesia and anesthesia may appear to be, and even as we shall observe, however fluctuating they are, from emotion and psychic causes, the fundamental basis is no less physical and no less dependent upon a physical substratum.

In a recent paper[37.1] we have introduced evidence that in the more severe (fatal) shell shock cases, congestions, ecchymoses, punctiform hemorrhages, softening of tissue environmental of superficial blood vessels of the brain and contiguous nervous structures are found. We may find similar anatomatical states among wet brained alcoholics and among cerebral softenings of general paralysis, but otherwise not at all among the great group of nontraumatic hystericals. We hold that shell shock and allied traumatisms damage the integrity of the body tissues in general, and thus disorder the mental functions which we hold does not proceed exclusively from the brain or nervous system. Our evidence shows circulatory deflections which could alone account for the tissue softening and attained impermeability to blood in the delicate brain tissues which require for their physical and functional maintenance one-fifth of the blood of the body. As we shall see presently, the effects of *suboxidation* of gas toxemia, of acidosis, etc., and of *suboxygenation*, respiratory, anemic, circulatory, etc., produce general tissue softening. These are the factors that universally obtain, wherever these results occur. Whether traumatic or not, the typical "neurotic" manifestations also find expression. The more severe traumatic types differ in degree rather than in kind. All are physical, but none is specifically nervous. All are both mental and physical. They are indivisible into either one or the other.

Predisposition.—Psychiatrists universally recognize a general predisposing cause of neuroses, whether hereditary or acquired. What that causative factor is has never been identified, much less agreed upon. The pure psychicalists must regard it as psychical, while with the physicalists it must be regarded as physical; yet with both it has ever been an enigma. By virtue of the effect of this inherent predisposition those affected by it are predestined to succumb to all manner of recoil producing factors, from which those uninfluenced by it escape; and the more violent factors from which none escape entirely, the predisposed suffering much more violent reactions than the others. With them the reaction is both precocious and excessive.

The essential character of reaction of the neurotically predisposed is typically spasmodic and paroxysmal, owing to which its victims are not only disposed to emotions and the other neurotic stigmata, but also to the more undisputed purely phy-

sical phenomena such as neuralgias, myalgias, asthma, etc., of the older writers, and now since we know that neuralgia, no less than neurosis, is a misnomer, we recognize dermalgias, coxalgias, myosalgias, arthralgias, cephalgias, nephralgias, cystalgias, coelialgias, thoracalgias, pleuralgias, hysteralgias, etc., more accurately named in reference to anatomic involvements; all characterized by spasmodic and paroxysmal pains and due to acute cramp like contractions of the involved tissues.

The physical nature of spasms and paroxysms has never to our knowledge been questioned, but Charcot and his pupils (originally entirely subscribed to by Sollier and others who have since deflected from it) so far as we know, concluded that all hysterical and allied manifestations have a purely *psychic* origin as evidenced by the following data: (1) Absence of any typically related lesions of nerves, cord, or brain, and of atypical areas of involvement as regards conformity to nerve trunk distributions. (2) In the absence of *nerve* sources of causation, hysterical paralyses and contractures must be of *psychic* origin. (3) All hysterical manifestations are artificially produceable by suggestion in sensitive subjects. (4) The anesthesia of hysteria is an *absent-mindedness* and is due to psychological disaggregation and is not always a genuine tissue anesthesia. (5) Arousing of the attention may momentarily hold the anesthesia in abeyance. (6) Genuine anesthesias are usually due to nerve lesions, whereas hysterical anesthesias are especially characterized by mobility. (7) Anesthesia of hysteria is extremely changeable and contradictory. (8) All hysterical events are dissoluble by chemical anesthesia. (9) Hystericals are in a permanent state of psychic fatigue. (10) Hysteria is a contradictory disease, and collectively is essentially *psychical* as distinguished from the *physical*, which is treated as of the nervous system if at all, but leaves the biologic factors out of account. Let us recall here that Sollier now defines the war neuroses (cerebral commotions), as hysterias in the raw, as elementary hysterias in which the physical as distinguished from the psychial element, is absolently preponderant.

Taking up this series of statements of evidence in the order above enunciated, the first and second have been answered by our biological accounting for what the psychical theorists reasoned must be either psychic or nervous in origin, entirely disregarding fundamental irritability and its response recoils; (3) Suggestion, like all sensorial impressions, is reacted to by subjectively related tissues, therefore the reaction is generally physical rather than specifically psychical yet not nervous; (4) however complete or incomplete the hyperesthesias that are exhibited, admittedly they are the physical causes of the abolition of memory, which again is admitted as responsible for amnesia. The fact that anesthesia of the contractile tissues of the body inhibits memory involving the original functional participation in that of which the memory is the recurrence by those tissues, implies that memory is not an independent or exclusive brain function, but a functional product of general tissue reaction which may be subject to a reactional revivification. In the treatment of amnesia and other diseases of memory the true seat of memory should be recognized regardless of any soul seat sentiments; (5) distraction is a form of suggestion, and suggestion is a recognized form of influence of contractile phenomena as well as of psychical; (6) loss of general tissue functional integrity and of density accounts for this observed mobility better than any known psychic factors. (7) The instability and fluctuation of tissue spasms explain the changeability and the elusiveness of hysterical anesthesia better than otherwise unexplained psychic caprice. (8) Artificial anesthesia admittedly acts upon tissue but we have no evidence of a separate action on mind. (9) We have no evidence of mental or nervous fatigue apart from associated contractile reactions of tissues. We have here pointed out the general relation between anesthesia and fatigue. Recognizing attention as a tension, as a state of intensive sustained effort, we can understand that momentarily eliciting the attention would necessarily transiently arouse a subject from an incomplete, even a drug narcosis. (10) is answered by answers to (6) and (7).

Fixed ideas of the hysterical series of stigmata, constitute a form of tetany, a mental catalepsy, and in terms of contractility, a rigidity or contracture of involved tissues. In this relation the idea is abruptly acquired as a spasm and is retained as a tetany. The *conviction* of Jastrow[34] is the *fixed idea* of Carpenter[r], Charcot[r], Janet[35] and others. In the the words of Jastrow: "There can be no question where beginnings lie. The original source of conviction is emotion. . . . The initial factor in the genesis of conviction is the rivalry between reason and emotion. . . . The design deviates, the workmanship is irregular, as thinking is emotionalized. The wish is father of the thought and breeds true. Dogma and formula, formidable words, like popular slogans help to carry conviction, they are more apt to contribute to obvious fallacy and pretence than to subtle error, but they play their part variously.

Conviction, the snapshot, the immature grasp at an idea, is exhibited in inverse ratio to reason which is the product of mental elaboration, *i.e.* of an extended deliberation. Ideas derived by spasm are those which are prone to persist as fixed ideas. Fixed ideas are thus common to the recoil spasm of shell shock.

Decision by Paroxysm.—There are obviously at least two ways of arriving at a decision, by process of reason, *viz*, by weighing the pros and cons of available evidence and by spasm or paroxysm. By process of producing the sudden emotion of fright, an individual may spasmodically in connection therewith arrive at the conclusion that an impossible dogmatic belief is truth or superior to truth. A fixed idea is as persistent as the underlying hyperesthesia.

The greater the abruptness, haste, stress, dynamic violence of a decision, the moment it is adduced by passion, the greater the attendant emotion of fright, anger, rage, etc., and the more spasmodic and less reasonable it is. An emotional decision is always premature and ill advised, and rash are the acts that proceed therefrom. When a decision is arrived at spasmodically it is thus termed *conviction*, it is perpetual as a fixed idea, a belief. The scene and event incident to shell shock is thus perpetuated as a fixed idea. The term conviction, which originally

had reference to the resultant of convincing evidence or perhaps of logical argument, has gradually by misuse, evolved from a state of being convinced, to one of being emotionally and spasmodically transfixed, obsessed (brought to an abrupt decision), attained as by a sudden muscular cramp. The transition is one from a gradually elaborated, to a sudden mental process, and as such, from a constructive mentation to a destructive annihilation or extinction of deliberation. We have in hypnotic processes the best analogy of artificial production of those fixed ideas which are dictated or arbitrarily commanded by another, in either a waking or sleep state. Suggestion acts as a shock.

It is precisely the spasmodic nature of the process of attainment of fixed ideas that makes its cause simultaneously productive of an anesthesia of areas involved in the volitional events of daily life, in the abolishment of memory of those events, and the muscular processes involved in them. In turn, the abeyance of memory in the mechanics of these processes constitutes the basis of the syndrome of amnesia. Whereas fixed ideas are not infrequent accompaniments of amnesia, the latter by no means universally accompanies the former. They represent variations of effect from the same causes.

Fixed ideas are also typical of ecstatic states, and we have been taught to regard the involved thoughts as very high in that state which have undoubtedly misled many from a theory such as we have advanced. Janet, however, disagrees with them when he observes (p 391): "M. Briquet spoke of the 'serious thoughts' which provoke ecstacy. This is because he had perhaps not been able to determine the nature of these thoughts. We much fear that many ecstacies among the most revered, have never thought of anything higher than the monotonous interrogations of Marcelle or Maria."

It is quite universally recognized that ecstacy and emotion produce or coincide with anesthesia, abeyance of memory, and of reason, and it is quite obvious that with the obliteration of memory from current mental synthesis, with the usual substitution of subconscious groups, the quality of the product would be low. Even in cases where complete amnesia is not developed, it is well known in police circles that following the great emotion which is incident to accidents and exciting escapades, that individuals are woefully deficient in memory of the details of the incidents of which they were the participants. In these cases confusion of attention, as well as sense anesthesia, is exhibited.

The fixed idea is a prime menace to recovery from shell shock and the depressing emotions of war. It is the essential element that disposes to relapse when new experiences recall memories of original occurrences and distressing scenes. The eradication of the fixed idea is one of the great services which hypnosis has rendered to war victims. It is thus eliminated from the subconscious ensemble of memories, in many cases having long previously been dropped from conscious memory, at the outset of the amnesia.

We do not advocate dispensing with hypnosis where it is of value in behalf of the war's afflicted. We simply deprecate it as an exclusive dependence as based on the view that the war neuroses are exclusively psychical and do not require physical treatment. In properly selected cases hypnosis has no equal and in some cases it has no possible substitute at all. It is hypnosis or neglect. It should, however, always be administered with the patient's written consent, and always in the presence of dependable witnesses, yet utilized when the subconscious and forgotten engrams which amnesia has removed from conscious memory must be reached and restored to normal consciousness. Many of these cases can be reached by psychoanalysis.

The Biologic Series.—The biologic series is a term we have coined to facilitate economy of expression in referring to that very familiar biologic series of reaction manifestations which always occur in definite sequence and order as typical response phenomena of living tissues. This term is used as regards the definite order of reaction characteristics which are typical of definite phases of tissue density, both as contractile and as sensory reactions. The sensorial application we will defer until that subject is arrived at in the regular course of the paper.

We may excite the several phases of the series, in their natural order as contractile phenomena. If, beginning with a normal state of rest, an excised living muscle be mildly stimulated, preferably by electricity, the first observed response is a simple tightening of the fibers. They are put in a state of tension, as it were, and such a tension can be maintained without producing a perceptible shortening of the muscle until exhaustion flaccidity occurs.

The next step is producible by a slightly increased perturbation, in which the response contraction is incomplete, giving it a twitching character. The next, following a sufficient excitation, is a complete contraction. These phases which may be regarded as ascending reaction types, and may be varied in time relation by the time duration of the stimulus, represent the ascent from the state of rest to the contractile climax. If we continue a sufficient stimulus to maintain a continuous and unremitting (or tonic) contraction, we observe after a variable time, depending upon the vitality of the muscle, that the integrity of the contraction begins to break and a manifestation of broken integrity of contraction as a descending curve from the climax, thus occupies a transition stage extending to final exhaustion relaxation and flaccidity. The hysterical epileptoid and *grand mal* of complete epileptic paroxysms represent a passing through an analogous series of successive reaction phases. An emotion follows a similar course, a miniature of the major paroxysms, developing tensions of greater or lesser degree, but aborted by precocious overflows or emissions. The hysterical paroxysms, their catalepsies, contractures, constrictions, etc., represent yet more complete contractile phenomena, and the painful contractions, the various paroxysmal affections, asthma, etc., and the acute *algias* characterize the climax stages. Thence succeed clonic contractions and exhaustion flaccidity.

Convenience of consideration and comprehension of these physical states is greatly facilitated by assuming hypothetical phases of tissue reaction, in the order of the biological series as the tissue density reaction equivalents of various definite manifestations, such for example as the progressive hyperesthetic reactions, respectively, of tetany, twitching,

tics, catalepsies, contractures, clonic convulsions, flaccid paralyses, etc. We can then better understand the action of the various therapeutic measures at our command, and that those that change the pathological phase should be differentiated into those that restore the normal tissue synthetic processes, the density and the integrity necessary to functional capacity, on the one hand, and those which by toxicity or other agencies carry it forward to the exhaustion stage. The former is physiologically progressive. The latter is one of pathological retrogression. Though they are equally efficient in eradicating disagreeable symptoms, the ultimate resultant of the former is good, the latter, bad. In the treatment of shell shock, not infrequently symptoms are transiently eradicated by measures such as chemical anesthesia, which do not eradicate the underlying hyperesthesia, and even predispose to relapse when the victim experiences a subsequent shock. Ultimate reflections on these points is sure to bring severe condemnation on those who are responsible for such shortsightedness.

The typical emotion paroxysm, which may be but a miniature of the developed hysterical paroxysm, may range from a simple disturbance of the respiratory rhythm by a prolongation of the inspirations, to even treble that of the expirations. It may be attended by a sobbing form of breathing and accompanied by successions of waves of emission of kinetic energy expressed in ripples of miniature muscular contractions, passive, involuntary, largely insensible to the subject, and affecting mostly the smaller muscles and those of expression more than of posture or movement, ranging to conversion or hysteric types and to motor discoordinations. See Darwin and Bell later on.

Next to emotion, the choreic reaction exhibiting the biological phase of twitching, or incomplete muscular reactions, is expressive of reactions modified by weakness. It is truly an irritable weakness of the soft tissues of childhood, which may be so hyperesthetic that muscular repose is impossible and superirritability agitation is the inciter of involuntary incoordinate movements. Here we observe energy accruement beyond that of the early emission of the emotions, but less than that of the complete tonic contractions. Chorea exhibits movements which in discoordination of movement resemble those of the adult amnesia. Tremor exhibited either in sustained effort or motor activity is to be recognized as a weak and imperfect exercise of the muscular organs.

All the specific types of vital reactions exhibit a succession of dominant phases in the biological series, followed by relaxation attended by an exhaustion relative to the expenditure of energy. Emotions vary greatly; the passive pleasant emotions are hardly more than thrills of passing waves of mildly excited sterile impulses. Those of the passive perceptions of music, dramatic performances, speed exploits of airplane and automobile, are those in which the auditor and passenger play an entirely passive part. Here is especially observed an instance where the emotive or amotive feature would be eliminated if the mechanical work of expression or propulsion necessary had to be supplied by the auditor or passenger. These pleasant emotions are accompanied by those transports of delight and of sensorial lulling which are akin to those of religious ecstacy and certain lesser degrees of drug narcosis, of alcoholic intoxication, and chemical anesthesia, all of which are pleasing and captivating, analogous to the passive stimulations of massage.

The distinguishing feature between the socalled *conversion* hysterias and simple emotions, is the contrast between the more or less imperfect physical expression in the former, and the sterility of the latter. All kinds of impulsive and explosive acts are characterized as emotional when really hysterical would be a more distinctive term. They belong to the conversion type of hysterias. The term emotion should be restricted to the less motor and the more emissive and sterile types.

The recoil, or unpleasant emotion, follows more perfectly the characters of reaction irritability. The emotional addict being in a state of low energy cumulative capacity, the emotion as a recoil phenomenon begins in the biological phase of the persistent state of tension which may develop into a tetany; examples of which are dry grief, restrained rage, tetanic fear, etc., which exhibit delayed relaxations and accrued ultimate outburst force. The more typical emotion, however, is the type which is characterized by little development of tension, and which is being continually released by waves of emission of escaping physical forces. Emotion may emerge into hysterical paroxysm as physical motive forces accrue to explosive outburst.

Every normal individual unconsciously experiences a continuous succession of recoils to his environmental vicissitudes, which, though more or less wearing upon the vitality during waking hours, do not arrest the attention or cause conscious fatigue. If, however, the individual becomes hyperesthetic, these same series of recoils, formerly entirely unnoticed, now become exaggerated and a source of perturbation of conscious irritation and chronic fatigue. If, on the other hand, a mild narcosis or anesthesia or an ecstatic state be substituted, the release from what has been an unperceived factor is now characterized by an indescribable feeling of relief, of freedom, and a mysterious emancipation which is attended with a physical sense of buoyancy, lightness, and relaxation, and a mental one of peace, serenity, blissful comfort, rapturous delight, or transports of felicitous pleasure. As this passes away the previous insensuous perturbations become perceptible.

In other words, the state of lulled sensibilities is one of imperturbation from environmental factors. Not until one has experienced narcosis or anesthesia, which obliviate the subject from the normally imperceptible factors, does he become conscious of their existence. It is then to some degree, by contrast with the anesthetic abeyance of sensibility, that it is apprehended, though the toxic features of the drugs must also be recognized. However, the typical after event is a heightened acuity of sensation.

A Biological Substratum.—So many cases have been reported wherein soldiers have experienced serious results from a second or third shell shock which were out of all proportion to the current shock, that interest attaches to the underlying cause. After discounting the factors of aggravated irritability, augmentation of the exciting cause, super-

imposition of one causative factor upon another, increased fatigue and weakness, etc., should cause us to give heed to the biological factors of causation.

In biological research on elementary reactions of rudimentary forms of life, involving the fundamental property of irritability of living substance in general, it is observed that if the excised living muscle, in a state of rest or quiescence, be irritated or stimulated, and after an interval reirritated or stimulated, the same in kind and degree, whereas the first stimulus excites no appreciable reactions the second one will excite one, both precocious and relatively violent. The first reaction, in fact, falls below the physiological unit, *the threshold of stimulation*, and the second greatly exceeds it. The first stimulus sensitizes the object of observation sufficiently to produce a hyperesthesia. This fundamental biological factor should not be ignored in our analytical efforts in behalf of elucidating the many seeming paradoxes of the war neuroses.

If instead of occasional intervaled perturbations a reasonable succession of perturbations occur, the above-mentioned result will not materialize, but instead an immunity will be developed, protective in its nature. Again, if the succession of perturbations be so rapid or frequent that the reaction of one cannot be completed before the accession of the succeeding one a state of coalescent contraction supervenes, termed biological tetanus.

Recurring now to the battle line, we find the first described type among the victims of occasional big-shell explosions; we observe the second type among those of the more frequent ordinary field-gun fire; becoming accustomed to it, we attain a degree of immunity which minimizes the effects of the explosions of close proximity when they occur, which are often referred to as paradoxically inconsequential. If, however, the firing assume the high frequency known as drum fire, the most unhappy results obtain.

It is well known to embryologists that fertilized eggs, subjected to the vibratory jars and shocks of railroad shipping, when later hatched exhibit a delayed development. In many it is completely arrested. The coarse vibrations of electricity prove fatal, whereas the same voltage in very high frequency currents is withstood with impunity. The living substance thus appears to be vulnerable to coarse vibratory perturbations of extended wave length, on the one hand, and of overlapping and coalescing ones on the other. Drum fire has been much observed as a prime factor of shell shock etiology.

Suboxygenation and Suboxidation Factors.—There are many occurrences connected with its occurrence that point in no uncertain way to the conclusion that suboxygenation and suboxidation play a prominent part in the production of the composite syndrome of war shock. Primarily, let us recount the three prime essentials of all oxidation, namely: *Oxygenation* (the supply of oxygen), a definite alkaline reserve or *alkalinity*, and a radioactive activation to chemical action at a relatively lower temperature than otherwise would be the case, termed *catalysis*. On oxidation collectively is fundamentally dependent the process of tissue synthesis.

Physiological catalysis is provided by the cell neuclei of the stationary tissues and by a highly neucleonic substance, viz., lecithin, of the circulatory tissues. A supposed poverty of these tissues, or of their phosphoric content in neuroses and psychoses, especially the former, has led to the well-known phosphorus form of internal medicine in this class of cases, and to many artificial catalytic substitutes in the form of radioactive and allied therapeutic measures. We learn from Hamberger's law that phosphates and albumins are given up altogether as cleavage products of the blood when it is even slightly acidulated, or carbondioxide is passed through it. General acidosis is already well proved to be a product of shell shock and a constituent of its syndromes, by competent investigators, recently reviewed by us, and it now remains to point out the *suboxygenation factors.*

As a beginning, let us concede that all cases of peripheral and extremity anemia and asphyxia and splanchnic venous stasis are conditions of marked local and general suboxidation, whether occurring with emotions, hysterical paroxysms, or war shock. Fatigue, as a predisposing cause, we know may produce albuminuria and phosphaturia, and fatigue products in excess produce general toxemia. Physical exhaustion depresses both the respirations and circulation.

The collective physical phenomena attendant upon near-by explosions of large high-power shells are almost without exception suboxygenational or suboxidational in action upon animal life, if the men who have made the subject a scientific study throughout the progress of the war are not discredited. There are too many creditable eye-witnesses to discredit them, whatever be our interpretations. They will ultimately demand a hearing.

The atmospheric disturbance may be perceived from Col. Sir John Collie's statement[5] that a high explosive exerts a pressure of ten tons to the square inch. Major Frederick W. Mott[5a] comments that *enormous aerial compression is generated, the ordinarily incompressible and hence protective character of the cerebrospinal fluid is altered, and it is therefore probable that the compression is transmitted to the fluid about the base of the brain, causing shock, affecting the floor of the fourth ventricle, and resulting in abrupt arrest of the cardiac and respiratory functions,* which is significant, though highly speculative as to the nervous mechanism.

Major Mott,[5a A] after crediting Sydenham with the statement that the forces generated are sufficient to cause instant death, and another's estimate that the sudden atmospheric depression of such cases corresponds to a dynamic pressure of about ten tons to the square yard, comments: "One effect of this is to liberate nitrogen suspended in the blood and transform it into bubbles of gas, which are driven into the capillary vessels and cause instant death." This effect is distinctly deoxygenative.

In his Lettsomian Lecture No. 2, Major Mott remarks: "Many of the symptoms of CO poisoning are similar to those which I have observed in shell shock and burial." In his lecture No. 1 he mentions that one may be buried and partly asphyxiated, or suffer from deoxygenation of the blood through CO poisoning, of which high explosives contain so large a quantity.

Returning to lecture No. 2, he continues: "The symptoms of CO poisoning are headache, which may take the form of distention of the head without pain, ringing of the ears, interference with vision, which may become indistinct and blurred, hallucination of sight, and even blindness, giddiness, especially on exertion, powerlessness, yawning, weariness, often vomiting, shivering and feeling of cold, palpitation of the heart, and feeling oppression in the chest. When men regain consciousness they appear dazed and stupid, and generally have no recollection of what has happened," etc.

Proper facilities for prompt artificial oxygenation of badly asphyxiated cases should be convenient directly behind the battle lines, and not only by inhalation, but in comatose cases by gas pumps, through colon tubes per rectum. Many cases can be saved in this way that otherwise would be partially or wholly lost.

A very important derangement of the mind in CO poisoning is loss of memory. This may be characterized by intense retrograde amnesia, together with loss of recognition. Sometimes a whole period of time is effaced from the mind. The power of speech may be lost for some time, or it may come back after many days. This symptom amnesia is as typical a resultant in other cases involving other types of suboxygenation and acidosis.

Major Mott's résumé of the effects of high explosives: "(1) Commotion from aerial compression, (2) concussion, with or without burial, (3) decompression, with embolism by bubbles of N and CO, (4) inspiration of CO during the aerial compression, (5) prolonged inhalation of noxious gases while lying unconscious or partially buried.

Mott quotes Leonard Hill: "Explosion of a big shell in a trench, dugout, cellar, or other confined place, must, I think, instantly deoxygenate the air and produce a high concentration of nitrogen." This is again deoxygenation to the victim.

The importance of burial as a factor of suboxygenation is emphasized by reports such as one made by Dr. McCurdy[10] of a British soldier who one night was buried, and was under the earth for three-quarters of an hour. The immediate and later symptoms of this case were described as of a most serious nature.

Feiling[11] reported a case of a bandman who was buried in a trench for probably twelve hours before being dug out, whose amnesia (loss of memory) was so complete that he was oblivious of his past life, home, family, friends, etc., which, however, were preserved in the subconsciousness which he gave outward expression to under hypnosis, thus exhibiting a double personality, each one oblivious of the other. No CO poisoning was reported in this case.

Sollier and Chartier,[12] among the other clinical analogies of shell shock, which vary as to cause only, also recognize caisson disease as a sort of counterpart of its mechanism. The sphere of influence in cases of shell shock is divided into three zones by these authors. In the first the subject experiences a blow proceeding from the displaced air, and of such violence as to be comparable to a blow from a solid projected with great force. The sequence in this zone is generally fatal, from gross injuries, fractures, dislocations, cerebral and medullary lesions, organic injuries, etc. In the second zone a primary great atmospheric compression, characterized by sudden increase in its density, is followed by a secondary event, a violent atmospheric expansion (decompression) caused by the vacuum produced by the explosion. Gas embolisms are attributed to the expansion phase, and by analogy with caisson disease, cases of hemorrhage, rupture of the ear drum, labyrinthine ear shock, retinal hemorrhage with choroid rupture, paraplegias and hemiplegias are also charged to this, which is also the injurious phase of caisson disease. In the third zone the body is subjected to rapidly decreasing vibrations compared to electric vibratory phenomena, and comparable to electric shock and stroke by lightning.

The authors put the question: May not paralysis, contracture, tremor, anesthesia, etc., be due to inhibition, or to exhaustion caused by excessive stimulation of the sense organs or nervous system, or to a molecular disturbance of some kind produced by vibration in the equilibrium of the nerve cells?' Let us add: Is not this inhibition one of spasmodic anesthesia? Are they not physical—contractile?

We will quote the translator's and author's résumés: "In cases of shell shock, then, are present from the outset nervous disturbances of a purely functional aspect, to which may or may not be added organic lesions, generally temporary. At the end of a certain time the same symptoms are formed that belong, in the large majority of cases, to hysteria. The authors believe that this hysterical phase is not a distinct element, nor a superimposed condition, but that there exists in these cases a scale of operating factors, physical, mechanical, organic, and psychic, all tending to produce a single clinical result. In the hysteria of shell shock, physical causes and conditions predominate; in ordinary hystero-traumatism, psychological and physical phenomena are on almost the same plane; and in ordinary hysteria the psychological element tends to assume a dominating importance.

As to prognosis, it must always be attended with great reservation and circumspection.

As to treatment, as soon as the organic disturbances disappear the problem is simply one of traumatic neuroses, lacking the psychic element.

The authors draw the following conclusions:

1. The kind of explosion determines the number and variation of its results.

2. The clinical manifestations resulting do not present a definite character, for they are found under other conditions. There is, therefore, no syndrome peculiar to shell shock alone.

3. Some of these manifestations appear to be due to distinctly organic disturbances, others to dynamic disturbances of the central nervous system. The former seem to be caused by the shock and the violent atmospheric expansion, the second by atmospheric vibration.

4. Between the clinical syndromes of a purely organic nature and the functional manifestations exists a series of transitional forms, which fact leads to the conclusion that the central nervous system is subject, with a different degree of intensity, to both types of symptoms.

5. The nervous symptoms of the functional type are found most often, from the somatic point of

view, with the characteristics usually attributed to hysteria, as described by Charcot.

6. These symptoms exhibit hysteria in its most spontaneous and elementary form, lacking absolutely the psychological complex that ordinarily complicated and colors it.

7. They prove that hysteria can be of a purely physical origin, without the interpolation of any psychological process whatever, conscious or subconscious.

8. Psychological theories of hysteria are, therefore, insufficient for explaining all cases. Only a physiological interpretation is applicable to hysteria from a physical cause as to hysteria from a mental or moral cause."

As opposed to the able observations and analyses of Sollier, Babinsky[2] differentiates all so-called functional disorders into two varieties: those which are readily cured by psycho-therapy, and those in which he thinks the patient is opposing recovery. He questions whether those not curable by psychotherapy should not be refused discharge or sick leave. It is obvious that such narrow considerations as these lead to much harm. Not that discharge and sick leave are desirable, but rather the implied suggestion that unless cured by psychotherapy (since he recognizes no organic or physical damage), the patient must be a malingerer or a disloyal resister of recovery. In contrast with this, Sollier recognizes the existence of a *fixed idea* of incurability on the part of the patient, which he makes a subject of treatment and cure. It would seem an injustice to the patient, and the physician should not be too prompt in bringing him under suspicion before he has exhausted therapeutic possibilities outside of his own convictions (fixed ideas). Where optimism is high, when offensive is successful, much can be disregarded, but protracted trench warfare in winter makes it unsafe.

The Fatigue Factor.—The fatigue factor of the war neuroses is by no means an insignificant one. It calls for individual consideration, notwithstanding that its etiologic factors are by no means entirely separate from the other causes elsewhere treated. Farrar[10] has commendably retrospected the monographs of Bonhoffer,[35] Buzzard,[39] and Maitland[40] on fatigue and other factors of exhaustion, and exhaustion neuroses and psychoses.

The premonitory signs, such as irritable weakness, restlessness, insomnia, debility of attention, emotional instability, depression, etc., indicate hyperesthesia involvement with beginning exhaustion. Optic and auditory hallucinations exhibit super acuity of hyperesthetic reaction. The increased instability of muscle and the mild neurotic symptoms, arterial sclerosis, etc., suggest chemical irritations and mild inflammatory reaction, such as accumulated acid products, would be prone to cause. The extreme pallor, low blood pressure, edema of lower extremities, somnolence, collapse, etc., suggest splanchic venous stasis; and the dilatation of the heart, emaciation, diffuse muscular atrophy, edemas, chronic phlegmons, susceptibility to tuberculosis and other parasitic diseases, exhibit advanced inhibition of tissue synthesis, with serious loss of tissue density, and of functional and resistance integrity.

The conspicuous feature of these cases is the persistence and permanence of the fatigue sequences. Such extremes are little seen, apart from the rigors and disciplined overfatigue and exhaustions of war. Recuperation following excessive fatigues and exhaustions is painfully slow, especially following collapse. If these cases be returned to the line without rest and recuperation, often of many months, relapse is prompt, and exposure to shell explosions is quickly followed by shell shock and greatly augmented incapacitations.

A great danger in these cases is the exhibited proclivity of medical men to be overimpressed by the so-called psychical factors of causation, such as the withstanding of unremitting bombardment, especially of "drum fire," and moreover the resultant exhibition of emotional instability, insomnia, hysteria, and other classical "neurotic" and psychical manifestations, and finally of exhaustion psychoses, tends to warrant the conclusion that the syndrome is essentially psychical, perhaps imaginary or simulative. This great injustice has been done to this class of cases by medical men of all the belligerent nations, by both omission and commission. In the latter Germany leads, but the manner of their treatment of the deported Serbians out-Turks the Turk in barbarity.

It should be emphasized that it is economically best, as far as possible, to keep within the fatigue limitations of troops. Germany has recently given us evidence that exhausted troops are poor fighters, Russia did the same in the Russo-Japanese war. When fatigue limits have to be exceeded, not only ample rest should be enjoined, but resulting acidosis should be promptly neutralized by sodium bicarbonate, and the faltering circulation should be activated by hot coffee or other stimulants; but food should not be allowed too generously until the fatigue crisis has passed. All suspicious cases of cardiac dilatation and venous stasis should be removed from the ranks and treated with ergot until on reexamination they are shown to be equal to any service assigned to them.

The fatigues and exhaustions of continuous physical recoils, tensions, strains, tetanies, etc., are those of the physical body, contractile in nature, and accompanied with accumulation of the excrementitious metabolic products which we term fatigue products. The nervous tissues are probably least concerned in them of any in the body. These toxic excrementitious products react upon the living tissues, and as poisons retard the synthetic processes, resulting in a lower grade of tissue integrity, which is exhibited by lower density of the solid tissues and by lower specific gravity of the blood.

Fatigue plays so conspicuous a part as an acquired predisposing factor that some writers emphasize the collective events of war which eventually exhaust or render the subject prone to shell shock, under the general term strain. Smith and Pear[29] regard "war strain" as a more satisfactory term for the whole syndrome than shell shock. The use of the word strain implies continued perturbations, and anxieties culminating in some sort of giving way or outbreak, as a cumulative effect, which in war is greatly multiplied. Strain expresses the stress experienced in a monotonous highly disciplined life which is attended by the withstanding of incessant firing, which highly excites, with all

responsive reaction, restrained or inhibited, until a contiguous shell burst affords the impetus to an explosive outburst of pent-up emotions. This factor should not be ignored, though it by no means constitutes the entire syndrome as our collective data show.

As producers of polyuria, the superstress of sustained mental effort, the strain of sustained motor effort, the stress of the mental strain of bombardment, the anxiety of apprehension and dread, the tetany of worry and the tensional depression status, are about equal. However usually recognized as diversely psychic and physical states, they are all causes of polyuria and of fatigue and exhaustion as well as of psychic symptoms. Fatigue augments the hyperesthesia of the hysterical, and may be the exciting cause of an accident.

As fatigue products accumulate and by their protoplasmic toxicity are productive of hyperesthesia, we observe inversely with the exhibited general superirritability a coincident benumbing of the muscular sense and often of cutaneous sensibility. The relation of this factor should not be ignored when summing up the participation of fatigue in the syndromes of the war neuroses. In hyperesthesia and anesthesia we have a connecting link between the physical and the psychical.

Anesthesia of Exsanguination Asphyxia.—Sensory retrogradation in order of *biologic series.* Anyone can prove to himself the fact that tissue asphyxia is productive of anesthesia, by the highly artificial process known as distilled water anesthesia, by virtue of hypodermic injections of distilled water into a circumscribed zone until it is completely distended with the water, producing pressure displacement of the capillary blood, as indexed by blanching of the area. This anesthesia is as complete as though an adequate solution of cocaine was used. It may be added also that general anesthesia is producible by respiratory asphyxia, though it is accompanied by loss of consciousness. Most individuals are however familiar with the production of anesthesia below the knee of the leg crossing over the other, in which the patella of the under leg makes pressure against the vessels underlying the uppermost leg. Clinical observation provides numerous instances of anesthesia of exsanguinated extremities, and localized and generalized anemia of the periphery. One of these is by the circulatory stasis of an esmarch bandage.

Partial mechanical anemia, however does not in direct ratio produce a partial anemia, unless it is very gradually produced. When at all abruptly mechanically produced, circulatory anemia is attended by a too paroxysmal type of contractile reaction. If well graduated, it is characterized primarily by tension and hyperesthesia, secondarily by twitching and paresthesia, thirdly by cramp (spasmodic tonic contraction) and dysesthesia or pain, fourthly by broken or clonic contraction or convulsions and partial anesthesia, and finally by exhaustion relaxation, flaccid paralysis and complete anesthesia. Between these five phases of a curve of the range from the normal to flaccidity and anesthesia, one may fill in all transitional gradations intervening them, thus completing an orderly series of vital reaction events common to all reaction of living parachymatous tissues and owing to which fact we have dubbed it the curve of the *biologic series.*

Tissue density, as an index of the existing degree of integration and physical integrity of the tissues, other factors equal, occurs in direct ratio to its blood supply. Every individual exhibits a state of tissue density which is commensurate with his maintained states of tissue sanguination, qualified by the quality of the blood, and every individual standard of tissue density carries with it a corresponding phase in the *biologic series* as to specific reaction characters. Physical reaction characters are as typical of unit densities of living tissue as are the physical properties of the chemical elements to their atomic weights.

The relative importance of air, water and food as constituents of the body may be gathered from the time honored physiological maxims: "We can go seconds without air, days without water, and weeks without food." The chemical state of the body finds its prime importance in that degree of alkaline reserve which is necessary to oxidation and other normal chemical reactions. Among others may be mentioned the salt equilibrium, which is so vital that tissue integrity depends upon it, though it also is specifically related to the chemical reaction as shown by Hamberger's law which provides that blood even slightly acidulated gives up albumins and phosphates to the serum, while conversely when alkali is added, chlorides are taken up from the serum by the cells. Moreover, carbon dioxide passed through it acts the same as the acid, and oxygen acts the same as the alkali, the former fostering *disintegration* and the latter *integration.* We may add further that the former lowers tissue density and integrity while the latter fosters them. We observe that asphyxia and acidosis are notable derivatives of the spasmodic procedures from chill, violent emotions, concussion. accidents, war shocks, etc."

Numbness results from emotions and anesthesia from yet more marked spasmodic contraction. Thus we observe a wide range of what have long been termed neurotic and hysterical phenomena as ultimate sensatory disturbances, varying from the numbness of emotional origin to the anesthesia of spasmodic and paroxysmal contractions. Emotion from the esthesia standpoint shades gradually into paroxysmal reaction. We can place no mark of demarcation between the two. Emotions lose their typical emotion qualities of reaction as they progress in morbidity and become more chaotic and less defined, as they approach the characters of simple paroxysmal reactions on the one hand, or as they retrograde into simple emissions of energy on the other. In other words as they become sthenic or asthenic of diverse extremes of character.

Hyperesthesia obviously occurs in various degrees, for all exhibited hyperesthesia is not sufficient to produce spasmodic asphyxiate anesthesia. Mott[9] observed that hyperesthesia is more common than anesthesia. He found both superficial and deep sensibility affected and in severe cases sometimes loss of sensibility to all forms of stimulus. Myers[9] reports observations of hyperesthesias and resultant over-reactions of increase of effective response. He has observed several cases in which the hyperesthesia has passed over into *hypesthesia*

and anesthesia. Like Mott, he observed great variations in sensibility, but saw a preponderance of hypesthesia and anesthesia—perhaps at later periods than Mott. These contrary reports lead to the conclusion that the two opposite states are really equal.

"Myers found about two-thirds of the cases of disturbed sensibility were accompanied by spontaneous or subjective disorders of sensation or of movement. Such disorders were often successfully traced to actual blows in the region in question from sandbags or other objects, or to the patient's fall after having been pushed or lifted by the concussion" (Transcript by Brown and Williams[5]). This agrees with observations of Mosso cited in my former paper.[37] We regret these vagaries of description, but are glad of the mention of disorders of sensation, however, not understood.

In the idiot, imbecile, hysteric, and the war shock victims, to the extent that normally involved functioning tissues lose sensibility of their own muscular reactions and to exterior sources of impression, we observe exhibited functional incapacity, both physically and mentally. This is most adequately exhibited in those unstable individuals who fluctuate from sensibility to insensibility and exhibit normality during the sensibility periods and corresponding mental and physical disability during the anesthetic periods. Yet, when anesthesia is artificially produced and the pathologic anesthesia is thus eradicated, the primarily abnormal condition becomes normal. This fact proves our postulate that the root of the abnormality is a hyperesthesia and not the more conspicuous anesthesia.

That the exhibited symptomatic anesthesia is the derivative of a spasmodic exsanguination of the affected tissue is shown by the well established fact that when spontaneously occurring, it is a product of those diatheses and stigmata which otherwise are productive of spasmodic and paroxysmal phenomena; moreover when artificially produced, those procedures which obviously promote spasmodic reactions, produce the ultimate effects and conversely such agents as anti-spasmodics, narcotics and anesthetics, instead of increasing the symptomatic anesthesias, anomalously, temporarily or permanently abolish them. In fact the abnormality is eradicated and as far as that abnormality is concerned, *a normal state is produced temporarily by an artificial anesthetic, or by hypnosis, by virtue of relaxing the tetany or paroxysm which was responsible for the primary asphyxial anesthesia.* Such artificial relaxations occasionally prove permanent and as such, cure of the ailment.

Secondary Tissue Changes.—Among apparent paradoxes presented on both sides of our subject may be mentioned the changes in involved tissues from pre-spasmodic states of low density as predisposing to paroxysmal types of reaction, to post-spasm states of high density, which Roy and Cobbett[38] observed in skeletal muscles as due to exsanguination in surgical shock following which a rise in the specific gravity of the blood was ascertained within an hour or two, and to rise so high that it flowed with difficulty except in the largest arteries; the intestinal walls meanwhile losing their density, becoming succulent and passively hyperemic. Complementary to the above mentioned reverse in direction of tissue density change, from the state antecedent, to that succeeding the shock spasm, we know that hyperesthesia proceeds while anesthesia as typically succeeds the outset of this median event. In other words the predisposing status, leading up to the spasmodic reaction, is hyperesthesia, while the ensuing effect as exhibited by those areas affected by the spasm is anesthesia, not infrequently of an asphyxial nature, otherwise partially so.

The next exhibited phase in the order of the *biologic series* is that of full tonic contraction. This may be local or general, transitory or protracted, and either painful or not, corresponding to the acuity of the cramp spasm. In general, the acuity of the contraction and of the pain is synonymous, the greater acuity appearing in the smaller muscles; those of the face and intercostal spaces being notable. The more intensive contraction is also exhibited in the more vulnerable extremities, such as the muscles of the calf of the leg and the extensors and flexors of the feet which are most subject to painful cramps. The muscles of the extremities, collectively, exhibit hysterical and hypnotic catalepsies, contractures and rigidities, and as tonic phases of hysteric and true *grand mal* epileptic paroxysms, in which it occurs following a tetanic aura largely affecting the thorax, the pharynx and larynx in their deglutition and respiratory functions, erectile swelling of the pharyngeal tonsil. This somatic tonic contraction is succeeded by a phase exhibited by its broken integrity (clonic contraction), which is intermediate in the progressive course traversed to the final goal of exhaustion relaxation, the diffuse collective contraction of the somatic body is seldom if ever painful owing to the diffuse dissemination of the contractile phenomena. The observation that the aura exhibits its perceptible beginning in the weakest organ appears to hold true at least when the weak organ is the stomach. The question of the existence of visceroptosis in the cases where it arises from the abdominal region is an interesting one. Certainly strong emotion and many epileptic auras appear to emanate from stomachs also exhibiting dilation, ptosis, tenderness, and often a sense of soreness.

Pleasurable and painful features of emotions are in fact phases of relaxations and more or less tetanic contractions, as in *feeling* in general, as muscular sense phenomena. Persistent anesthesia of the muscular sense involves a loss of voluntary activity and loss or abeyance of memory of past voluntary use of the motor organs, and involves current incoherence and incoordination. Anesthesia with nullity of muscular sense involves abeyance of memory of its past functional acts.

Ecstasy is perhaps the most elusive of the hysterical crises. It is at once radically physical and radically mental. It has been characterized as the most "spiritual" of all mental phenomena. The ancients, when in ecstatic states, saw visions and prophesied. This state was fostered by fasting until advanced states of anemia and general inanition were attained, and not infrequently it was augmented by free indulgence in wine and the crude forms of oriental narcotics. The typical feature of ecstasy is bodily insensibility and mental revery

in which inability to reason and to perform mental tasks is as marked as is the hyperesthesia of the body. A sense of walking on air, while in the waking or semi-waking (walking) state is typical of several other allied states exhibiting loss of sensibility not excepting alcoholic intoxication. Ecstasy is surely not a *material* entity, but it is obviously a *physical* state characterized by abeyance of a vital function, as the effect of pathogenic factors above outlined. The hallucinations, when exhibited, show an advanced pathologic state.

Phenomena such as ecstasy and the emotions appear to occupy a place on the borderline as transitional phases between the purely psychic and the purely motor, partaking at times of both coincidently, and of each alternately. They are characteristic expressions of instability and of frequent facilitated fluctuations from one extreme to the other, though obviously subnormal and typical of disequilibrium. Owing to this aspect they are in many ways atypical.

Ecstasy in many ways approaches amnesia as a state of loss of sensation, memory and reason though less permanent. Perhaps one of the best arguments against the identity of ecstasy and allied phenomena with purely *psychical* phenomena is the fact that they act in inverse ratio to one another. Capacity for intellectual tasks diminishes correspondingly as ecstasy progresses. Reason and ecstasy are incompatible, one must decline as the other rises. The development of ecstatic states must be cured before a victim of hysteria can be expected to resume his normal economic capacity. He can be cured by correction of the tissue density and physical contractile derangements that underlie his hyperesthetic and anesthetic states.

The present paper is the second of a series of three on diverse aspects of the War Neuroses. In the third article will be found a recapitulation summary and a bibliography for the second and third papers.

In the third paper the author will endeavor to analyze and interpret individually the several typical manifestations which collectively go to make up the characteristic syndromes met with by the army psychiatrists, as reported by them in the current literature.

THE EFFECT OF THE SELECTIVE DRAFT LAW IN THE PRODUCTION OF PSYCHOSES.

By HERMAN P. HYDER, B.S., M.D.,

WASHINGTON, D. C.

JUNIOR ASSISTANT PHYSICIAN, ST. ELIZABETH'S HOSPITAL.

During the present great crisis in the making of the world's history, when all the leading nations and many of the smaller ones, are being held in the throes of a deadly combat, there is an excess of strain thrown on both the physical and mental energy of each individual. It matters not what his profession or calling may be, he must assume some extra responsibility, and especially is this true of those who are engaged in the active military fields. By placing man in a position where he is subjected to a greater amount of strain, changes in his emotional sphere are inclined to take place. The sudden change in his environmental condition, being surrounded, so to speak, by an altogether different atmosphere, stimuli hitherto unknown make a very forceful impression upon his fields of perception. The immediate transfer of a person from the peaceful life of a civilian to that of an active participant in a life of a military nature may be followed by unpleasant results.

Crile has demonstrated that quite early in the history of the evolution of man the various kinds of stimuli when applied produced certain types of reaction. If we take the broadest viewpoint in the study of the relations of the individual to his environment we readily can see that his every effort is centered toward bringing himself into adequate adjustment with his surroundings. In order to bring about this adjustment a certain amount of nervous energy is required, the amount expended depending upon the nature of the task to be performed. Upon his ability to meet and cope with the situation in question will depend the nearness to which he approaches a specific goal.

The nature of his emotions plays an active part in deciding the course an individual will pursue and, should a psychosis intervene, his emotions will be an essential factor in bringing about its onset. It is generally admitted that heredity is an important one among the causative agents in the production of a mental illness, but it seems in many instances that the situation in which an individual is placed is the paramount factor in bringing about the psychosis. It is the writer's opinion that many of the men recently admitted to this hospital would have been able to make good adjustment had the situation been less difficult. Smith and Pear on Shell Shock say, "A psychoneurosis may be produced in almost any one if the situation be made difficult enough for him." Had there been no selective draft law doubtless many of these young men would have experienced no mental disturbance.

To the individual who is prone to excessive indulgence in alcohol the situation may be a factor in stimulating latent desires. The alcoholic's mental condition may be traced to a faulty parentage. A biological inefficiency may account for his failure to meet the demands of life and he may only take this method of overcoming some difficulty or of covering up some deficiency wherein nature has failed to supply. To those who lack a knowledge of the psychology of such a person he is nothing other than a moral pervert who needs to have imparted to him lessons of morality and who should be compelled to abide by them strictly; on the other hand to the student of mental disease he presents an altogether different personality. Some fundamental element which is a constituent of the normal individual may be absent in this particular person. His inefficiency may assume the form of one of the types of sexual perversion or it may occur as the loss of the normal sexual powers; however, it matters not in what form the deficiency appears, it is the unconscious desire of such a person to adjust himself properly by surrendering to the excessive indulgence in intoxicating drinks. His familial condition may be not altogether pleasant, and he

may hail with much pleasure the call to enter military life. This may be to him a great emancipation, but on entering the service he finds the situation to be more difficult and to flee for refuge is impossible. There is only one alternative. Alcohol now comes to the rescue and his indulgence ceases only when he is housed safely within the walls of a psychopathic hospital. The following brief extract from a case is an example:

Only a few weeks ago a patient was admitted to this hospital. He was a young man born under normal circumstances, free from hereditary taint so far as could be ascertained. His childhood and youthful days were uneventful, but in his early manhood days he selected as his companions other young men, some of whom were addicted to strong drink. In the course of events he became an indulger at intervals. When the time had come for his entrance into the military service he accepted it as an opportunity to free himself from his former associates, also, as an excellent time to liberate himself from the drink habit. He entered the military service, the demands were greater than those in his previous environment, he began to indulge in alcohol and did so almost continuously; the result was that he was admitted to this hospital only a few weeks subsequent to his enlistment. The above instance is only one of the many who take this method of meeting the extra demands of a military life.

The causative agent of this type of reaction may be traceable to the same etiological factor which brings about a praecox episode or other forms of psychoses. If the various classes of mental disease are studied from a psychoanalytic viewpoint it will be seen that probably every form of a psychogenic neurosis is due to some buried complex—factors hidden in the unconscious realm of the individual. Let these underlying forces be given full credit as causative agents, yet it is clear to the mind of the writer that the environment of the individual, at the least estimate, plays an active rôle in the onset of his psychosis.

A large percentage of the recent admissions to this hospital are young men who fall within the age limits of the various classes of dementia præcox. Many of these patients show a symptomatology not essentially different from the ordinary præcox case, while in other cases the symptoms are variable. Many of the latter doubtless would have been able to follow the ordinary pursuits of a civilian life without the development of a mental illness.

To Kraepelin belong the credit of having introduced new life into psychiatry. By a careful and systematic study of his patients for many years, by his clear insight into clinical conditions and especially by his independence of thought, he was led to step to the forefront and shatter the bonds which for many years had retained the old classification of mental diseasee. It was he who first welded mania and melancholia into one form of mental illness. He was also first to study the various types of abnormal reaction in the youth and adolescent, and to give to each a name that signified the type of disturbance present. While he did not go deeply into the symptomatology of the disease, yet to him the patient's peculiar speech and actions, the numerous and senseless remarks, the reptition of meaningless words—each had its own significance. Kraepelin even saw more than this. He perceived that dementia præcox should be divided into subclasses. Since his day many other writers have attempted to select a more appropriate name, but, as yet, none has been accepted. Other students of psychiatry have gone more into detail as to the symptomatology and they have given more extensive discussions of the patient's behavior, only with the result that the greater percentage of young people with psychoses have been classed as dementia præcox.

The psychoanalysts have done excellent work in bringing to bear the etiology of mental illnesses and in a great many instances their successes have been worthy of merit. Hidden complexes have been cited as the causative agents. They have even gone further beneath the surface than the mere discovering that some unconscious element does exist as a basis, but they have been able, in many instances, to demonstrate the particular event which was responsible for the disturbance in the intellectual field.

To quote Smith and Pear, "Emotional disturbances play a very important part in all psychoses associated with war." Let the reader imagine the emotional changes occurring in the individual who is just entering this new sphere. The soldier just entering military life is subjected to intense and frequent stimuli, hitherto unknown, day after day with no relief, all of which could be "vouchsafed for" were he in civil life; but which is altogether impossible to those engaged in military fields. On account of his inability to overcome some difficulty emotional disturbances develop. The difficulty may usher in the mental disturbance in one of the many ways. The first signs of his mental illness may be characterized by the loss of sleep from a variety of causes. He may be unable to sleep from worry over learning his drill, from thinking about his homefolks, or because of his change of environment with such a variation from his previous mode of living. Whatever the cause of this loss of sleep, it may be accompanied by unpleasant organic sensations, as the loss of power of inhibitions and the loss of the power of self control. Along with numerous other disturbances he may develop an irritability of temper and an emotional instability. The man who is experiencing these mental and bodily discomforts may for a time show no outward signs, yet there is an inward conflict present. It must be understood that the suppression of all external signs of an emotional disturbance is only the partial dominance of the emotions by the will, and we must also remember that only the skeletal muscular system can be controlled by the will, and not that belonging to the visceral system. While there may be no signs of disharmony in the voluntary mechanism, and it may not be present, yet changes may exist in the circulatory, the respiratory, the digestive, and the excretory systems.

Probably three-fourths of the patients recently admitted to this hospital from the different branches of the military service come within the limits of the selective draft law. Many of these

patients might have been classed as being borderline cases previous to their taking up a military life. They are young men who have spent their lives in country places or small towns, with but little education or none at all, and with but a limited knowledge of the world's events. They have resided in a miniature world and they have cultivated no desire to pass beyond its limits. Their sole ambition has been to live in the way their fathers lived. When they were forced to register and subjected to the call to service a mark was placed upon them; yet hope still remained until they were assigned to active military duty. In civil life these young men had adjusted themselves well, they had been self-supporting and in many instances they had actively participated in the support of their immediate families. Had they never been called to support and defend their flag in a foreign country probably no psychosis would have intervened.

Now, take a young man entering some branch of the military service and beginning a course of intensive training, he is subjected to an altogether different environment, discipline surrounds him on all sides, he gets no sympathetic words, and news from the war zone is reaching him daily. He knows the present, he can only surmise as to the future, and he is extremely doubtful what the end will be. In his meditations he debates the question of his destiny and a fear of uncertainty enters his mind. At first he meditates, but later on he worries over the unknown; but no solution is tangible. Smith and Pear on Shell Shock say, "Of all the varieties of fear, the fear of the unknown is the greatest." As the days pass the individual attempts to alleviate his fears, a conflict ensues within him, he labors vigorously to become master of the situation, yet his every effort is in vain. His emotions are victorious, his will power is overcome, and a psychosis is fully developed. The following brief summary of a case will serve for an illustration:

A white male, aged twenty-five years, admitted to this hospital on November 9, 1917. So far as could be ascertained no psychopathic determinants were present, except that some members of his family were "quick tempered and nervous." His father was a grocery clerk, and the patient was the third child in sequence of births. His school life began at the age of six and continued until he was sixteen. He completed a preparatory course, standing at the head of his class. He was fond of athletics, he made friends easily, but his family relations were not altogether pleasant. He did not get along well with his father and brothers, but he was exceptionally fond of his mother, stating that he was her favorite.

His mother died when the patient was about eighteen years of age. Following her death he left home and worked at various jobs, in the meantime changing his residence several times. When the selective draft law went into effect he was forced to register as an eligible for military service. He enlisted for service in the Regular Army, as he stated, "to avoid being drafted." Apparently he made good progress in the army, as he attained the rank of sergeant by the middle of his third month in the service. At the end of the third month he was transferred to the National Guard and was sent to a new cantonment. Here he obtained a two days' leave of absence, visited a nearby town and returned intoxicated. He was reprimanded for his disorderly conduct and on the following day he went absent without leave, made his way to a nearby town, but was apprehended by the military authorities. He was returned to his camp and he stated that he "faked insanity," became noisy and destructive, destroying furniture, windows, etc. He also "faked death" and would tie cords about his limbs in order to stop the circulation.

On admission to the hospital he was oriented as to time, place, and person, he was free from auditory hallucinations but he stated that previous to his commitment, when "they" shot him full of "dope" he could hear voices talking to him and he was filled with all kinds of delusions. He said he had drank all kinds of poisons, a bottle of Sloan's liniment, a bottle of tincture of iodine, etc., and that he would have killed himself by drinking inoculation serum had he not had forethought enough to advise the ward master of the psychopathic hospital to keep the container closed. He was extremely nervous and restless. He showed quite a degree of psychomotor activity. He was inclined toward circumstantiality in his answers and at times displayed a marked degree of irritability. He also showed mild unsystematized delusions of a persecutory type, with reference to the other members of the family, and he stated that the army officials did not treat him right, inasmuch as they did not give him enough clothing and refused to pay him the salary he was promised. There was marked disharmony between his emotional and intellectual spheres. Numerous mannerisms were in evidence and he showed a number of facial grimaces at the time of his admission, but he was fair in his dress and clean in his personal habits. He stated that on one occasion he had ejected a lieutenant from his quarters because the lieutenant had made homosexual advances to patient.

He made a very good showing in the entire mental examination, which was not attempted until about two weeks subsequent to his admission. He possessed but little insight into his condition, maintaining that his mind was clear and that he was sent here only for the purpose of being properly restrained. The other phases of the mental tests were passed with a percentage almost equal to that of a normal individual.

On his arrival here this patient received kind assurance that all was well. He was informed that he would receive good treatment while residing here, that he would be discharged from the service within a few weeks, and that when so discharged, he would be permitted to return to his home should his mental condition warrant it. He immediately began to show signs of improvement, a rapid adjustment was made and by the end of a two months' residence he was discharged from the hospital, apparently having reached his former mental level.

Many parallel cases with varying shades of symptoms could be cited, in which the men have made as rapid and adequate adjustment as the one given. Now the question arises, into which one of the classes of psychoses should this and similar types of reaction be placed?

These patients show a symptomatology indicating an introversion mechanism, yet, apparently, no signs of dementia are present. When they are free from the enviroment in which the psychoses developed, their recovery is rapid and complete. No trace of a mental illness remains. They are able to resume their former occupations, demonstrating an efficiency equal to that displayed previous to the date they entered the military service.

It is hardly possible without a further study of cases to reach a definite conclusion regarding this type of reaction. Many patients express themselves as having been desirous of entering the military service, others enlisted to avoid being drafted, and the remainder was assigned to duty. Every one liked the service, each was anxious to do "his bit," but difficulties confronted each individual in this new situation and adjustment was impossible. A thorough and systematic study of these patients will doubtless reveal the fact that the agent immediately responsible for the onset

of this type of mental illness is traceable to the military environment.

THE TREATMENT OF MENTAL DEFECTIVES THROUGH PHYSICAL AND MEDICAL MEASURES.

By E. BOSWORTH McCREADY, M.D.,

PITTSBURGH, PA.

PÆDOLOGIST, SOUTHSIDE HOSPITAL AND JUVENILE COURT OF ALLEGHENY COUNTY; CONSULTING PÆDOLOGIST DEPARTMENT OF NEUROLOGIC SURGERY, NEW YORK POLYCLINIC HOSPITAL; DIRECTOR, WILDWOOD HALL.

In order to facilitate discussion the term "mental defective" is used in its most inclusive sense, as applying to all those individuals who fail to measure up to an arbitrary norm of mental development, whether the defectiveness be inherent and organic, a temporary developmental phase, or whether it consists of a more or less isolated impairment of certain faculties or functions.

With possibly few exceptions all mental defectives are improvable, some to slight extent, others to an extent which renders social adjustment possible. There are none of you who are unfamiliar with individuals, who, apparently feeble-minded in childhood, have, after subjection to a proper environment, become self-supporting and as well able to direct their own affairs as their supposedly normal fellows. Whether these cases could ever have been properly considered mental defectives or whether clinical psychology would still find defects of mentality such as would classify them as abnormal is not pertinent to this discussion. (Clinical psychology finds defects everywhere but in its own methods and conclusions.) Most of us manage to exist fairly comfortably with defects which if apprehended would immediately consign us to an institution.

I have been particularly struck by the improvement following the administration of proper hygienic measures, fresh air, good food, regular hours, exercise, etc., as shown by the condition of boys committed through the Juvenile Court to Thorn Hill School, the Allegheny County industrial school for delinquent and dependent boys. Many of these boys were, on the initial examination, thought to be feeble-minded, some being considerably below the accepted three year limit of retardation, besides presenting characteristics of physical constitution and of behavior which would classify them as being of the inherently defective class. Later examination, however, showed a general improvement such as to render their status comparable with that of other boys whose normality has never been questioned. If such results follow the general application of hygienic measures, aided by educational and other training, the results from more intensive treatment should be much greater. That this is so I have to my own satisfaction adequately proved.

It has more or less been the custom to cater only to the physical needs of the defective up until the age of six or seven years, which is considered early enough to begin the application of special educational measures. I think that this is a grave mistake and that this custom has been responsible for many human derelicts who might otherwise have lived lives of at least moderate usefulness.

Treatment should be begun as soon as the child's condition is recognizable as one of possible deviation. It is not necessary to wait until stereotyped tests can be applied. If doubt exists give the child the benefit of the doubt by treating him as a potential defective. If not defective he will be all the better for the treatment he has received. Even in early infancy there exist manifestations demanding attention. The undersized, puny, asthenic baby is not merely a problem of milk formulæ, for it is not so much the milk that is at fault as the physical organization of the child. Defects of correlative growth and subnormal activity of vital forces demand stimulation. Under ordinary circumstances the factors included in the term nurture are sufficient, but here nurture not only must receive unusual attention, but must be supplemented through the entire period of infancy and childhood. Gastrointestinal disturbances must be avoided, as these occur with unusual frequency in this class of cases. Maternal nursing is highly desirable, but should not be continued unless all conditions are favorable.

The subnormal energy potential of the child is in many cases due to a like deficiency in the maternal organism, with consequent imbalance of physiological functions, including lactation. Through artificial feeding certain principles essential to growth (vitamines, etc.) may be supplied which would otherwise be lacking. In some cases treatment of the mother by glandular therapy will insure an adequate and properly constituted supply of milk. Sajous ("Our Duty to the Mental Defectives of the Present Generation," *New York Medical Journal*, April 1, 1916) advocates the administration of organic products to the mother during pregnancy, when, because of poor heredity or constitutional inferiority, there is reason to suspect that the offspring may be defective.

Further on I should take up the discusion of organotherapy at greater length. There is a tendency, particularly among people who depend for guidance upon the popular books on infant feeding and the baby departments of the magazines, to postpone unduly the time of giving foods other than milk and to give other foods in insufficient quantities, thus depriving the child of important physiochemical substances at the time when they are most needed. The eruption of the teeth is a safe guide.

It is hardly necessary to speak of the value of fresh air as a factor in growth. Fresh air is not simply a vehicle for oxygen ("Fresh Air in the Light of Recent Research on Ventilation" by C.-E. A. Winslow, Chairman, N. Y. State Commission); it exerts its beneficial influences through stimulating the peripheral nerve endings and thus activating all physiological functions, consequently the defective child should spend but a minimum of time indoors, but should eat, sleep, and live in the open air.

Water also is a therapeutic agent of no mean value. In the form of hot baths judiciously pro-

longed, and particularly the continuous flow, it is of marked value in allaying excessive nervous irritability and restlessness. The cold pack, cold sponge, cold douche, and cold shower are of great value in stimulating nerve tone, with consequent effects upon metabolism, development, and growth.

A neglected agent of great value is heliotherapy. In applying sun baths there is obtained, in addition to the action of the sunlight upon the tissues, the effect of peripheral stimulation of contact with currents of fresh air. The sun bath stimulates the peripheral circulation nourishes the muscles, vivifies the blood, and increases the hemoglobin percentage, thus stimulating cellular metabolism and incidentally the processes which favor resistance and induce immunity. The secondary effects upon nerve cell nutrition and (possibly) regeneration are apparent. To obtain the best effects the treatment should be continued until deep tanning occurs, as pigmentation seems to be a normal phenomenon of the defensive reaction. Heliotherapy, like other therapeutic agents, has its dangers if injudiciously applied; the proper application requires an exacting technique.

Massage is useful as a form of passive exercise in children of deficient psychomotor control and when combined with corrective exercises is a valuable aid in the correction of spasticities, flaccidities, contractions, hypotonosity, etc. The general physiological effects of exercise are too well known to require enumeration, but this valuable remedy is neglected at the very time when it is of the most use. Attention focussed too closely upon exercise in psychomotor development results in neglect of its other function, particularly at the age when most effective. There are none of the measures mentioned above which cannot be initiated in infancy.

There is a prevalent impression that purely medical and surgical measures are of doubtful value in the treatment of the defective development, yet the armamentarium of the physician and surgeon offers much that may be utilized. The beneficial effects of the removal of reflex sources of irritation such as arise from adenoids and diseased tonsils, eyestrain, phimosis, impacted cerumen, carious impacted and abscessed teeth, etc., are recognized. A surgical measure whose value is not yet sufficiently recognized is that of cranial decompression as practised by Dr. William Sharpe. To most, any mention of head surgery in connection with mental defectives brings up the idea of the old operation of craniectomy, of trephining, which is for various reasons not comparable with Sharpe's method, as any of you who would take the trouble to investigate would learn. This, again, is a measure which should be applied as early as possible, even within a few hours after birth.

In those cases of mental defect in which the presence of congenital syphilis can be demonstrated, even when it would seem to be the important etiological factor, antiluetic treatment does not have the effects upon development that one might expect; in spite of this, however, treatment should be continued until no doubt exists as to the eradication of the disease in the hope of at least preventing further degeneration.

There are few hypoplastics who do not present some vagotonic symptoms; for these the indication is for atropine in full physiological dosage. I have come to regard atropine as a most valuable aid in treatment, especially in the active, restless, and neurotic type of defectives. In apathetic, listless individuals nux vomica in ascending doses till full physiological tolerance is reached is of great value. There is a group of remedies which exert a very decided action in removing morbid conditions of the system and improving general well being, "agents which alter the course of morbid conditions and modify the nutritive processes while promoting waste"; the most important of these are mercury, iodine, and arsenic; they are very active and must be administered with care. They are rapidly absorbed and carried to the tissues, becoming intimately connected with the vital processes, and, escaping with the products of metabolism, are excreted by the various secreting surfaces. Their use should not be prolonged unduly, as they are liable to cause depression and weakness with irritation during their passage from the system. The use of alteratives is of particular value in the treatment of conditions of defective development, as waste material must be removed before new healthy cell growth begins. As the more actively this is carried on the more rapid will be the improvement, it is often advisable in cases in which the products of malnutrition have accumulated and the various organs and functions are inactive to combine the alterative with a more active eliminant such as the salines.

It is now generally conceded that the chain of ductless glands is of the greatest importance in the development of the cerebrospinal and osseous systems in early life, and that impairment of function of one or another of these glands underlies the disorders of nutrition which inhibit proper development. Under the caption "The Ductless Glands and Constitution," Falta says, "we must not accept the ductless glandular system for itself alone, but must regard it as a constitutional component; the ductless glands as vegetative organs together with the nervous system regulating their functions." While our knowledge of the normal action of these glands is still somewhat hazy, yet they are found to preside, in some manner, over certain correlations of the body. These correlations are exceedingly variable, and this variability is most apparent when and where circumstances are abnormal. The adjusting mechanisms of development are more or less reciprocal; thus a ductless gland not only influences development, but is itself influenced by changes in general development. There is reason to suppose that in the harmony produced through the concerted action of the ductless glands, the leading role is played by the thyroid, which supplies the stimulus for bodily metabolism. As a check upon the influence of the thyroid in infancy and childhood, the thymus, the general lymphatic system, and perhaps the pineal gland, become active. In addition, these produce that delay of sexual activity which is essential to the proper maturation and stability of the somatic functions. In due time the adrenal system stimulates the sexual organs to activity, and hastens as well the growth of the muscular and skeletal systems. Of great importance at this time is the action of the pituitary gland, which stimulates every organ of the body.

Belief in the important role played by the duct-

less glandular system in development and belief in the possibility of correction of developmental defects by measures calculated to stimulate or alter the action of the various component parts of the ductless glandular system does not necessarily imply that all such treatment should be through the administration of ductless gland substance or products. There is not one of the measures already mentioned in connection with treatment which is without its effect upon the ductless glandular system, either as a stimulus to function or as a stabilizing influence upon the system as a whole.

There exists a misconception which is fairly prevalent regarding the possibilities and limitations of organotherapy in the treatment of defectives. Those who are looking for a panacea or a specific will be disappointed. There are undoubtedly cases in which brilliant results follow the administration of organic substances, as thyroid in cretinoid conditions, anterior pituitary gland in dystrophia adiposis sexualis, the whole pituitary gland and thymus in certain types of infantilism, but these more conspicuous instances are the exception, as in most cases the implication is pluriglandular rather than uniglandular and is a part of a general hypoplastic condition rather than a clinical entity. For this reason the best results may be obtained by a judicious combination of the glands of internal secretion. When so used their effect is stimulation of all physiological processes and is analogous to that of the alteratives upon whose action when given together they exert a reciprocal influence. I am accustomed to use a combination containing small doese of pituitary, thymus, thyroid, and adrenal glands with the addition of testicular substance for administration to male children and ovarian and mammary substance to female children.

PERSONAL HYGIENE! HOW OLD, YET EVER NEW!*

By DANIEL E. DRAKE, M.D.,

NEWFOUNDLAND, N. J.

DIRECTOR IDYLEASE INN

Personal Hygiene! How old, yet ever new! What memories of the past, what hopes for the future! The splendor of Caracalla's Baths in ancient Rome; the Moorish fountains of Spain, mute reminders of a lost therapeutic art. "Mislike me not for my complexion," said the Prince of Morocco, reminding us that hygiene and care of the skin were not confined to the blond races by any means, but were brought to a high stage of perfection during the Moorish occupancy of Spain. In the great palace of Abderrahman, to which no less than 6,300 persons were attached, the Moors, retaining the love of their ancestors for the cooling effects of water in a hot climate, spared no pains in the superfluity of fountains, baths, hydriatric works, and artificial lakes. "To the Saracens," says the historian Draper in the Intellectual Development of Europe, "we are indebted for many of our personal comforts. Religiously, cleanly, it was not possible for them to clothe themselves according to the fashion of the natives of Europe, in a garment unchanged till it dropped to pieces of itself, a loathsome mass of vermin, stench, and rags. No Arab, who had been a minister of state, would have offered such a spectacle as the corpse of Thomas à Becket when his haircloth shirt was removed. They taught us the use of the often-changed and often-washed undergarment, which still passes among ladies under its old Arabic name (Chemise). In all the palaces, great care was taken to make due provision for the cleanliness of the inmates. Through pipes of metal, water, both hot and cold, to suit the season of the year, ran into baths of marble."

Such were the palace and gardens of Zehra, and such the opportunities for the personal hygiene of rich and poor in ancient Spain, full 600 years before there was a pavement or a street-lamp in Paris or London, and when our immediate Anglo-Saxon ancestors like Thomas à Becket were living in unwashed barbarism. To even emulate these ancient baths we have a long way to go, and it is fitting that we of the medical profession, whose New Jersey State Society I have the honor to represent as a delegate, should do all in our power further to foster and encourage the admirable efforts of your society. That in these matters of personal and public hygiene we are 800 years behind Saracenic Spain, 1,800 years behind the Romans, and untold centuries behind the Egyptians and Babylonians, should serve only to stimulate our emulation of these venerable nations. That we still have a long way to go before our public baths are on a par with those of the ancients speaks well, no doubt, for our future growth along these lines, pointing as it does to the extreme youth and immaturity of our civilization.

There could be no more timely hour than the present for the consummation of your laudable projects. Anguished Europe has found it necessary to provide for the hygiene of her people and the multiplication of public baths and recreation centers bear strong testimony to their worth. Let us have them here, and have them soon!

Within a year there will come back to us the great stream of injured soldiers which is destined to tax every possible resource at our command. Let us be prepared, for whatever the nature of the disability! We must remember that it will occur in the young—a factor of great encouragement and promise. For young tissues have a recovery coefficient far higher than old, and, whatever the lesion be—from morphine addiction to shell shock, tuberculosis, and syphilis, it is going to be worth our while to work, and work by every known means at our command for the restoration of these boys. Never in the history of the world will such well disciplined, concerted efforts be put forth in reeducation and practical therapeusis. Undoubtedly, the public bath will, under this pressure of the near future, offer to the community which it serves, as already intimated, more than mere bathing facilities. It will not only bathe, but build and educate the body.

Some historical references are pertinent. One of the advantages of the world war, will be in England: a rebirth of the community spirit and

*Read before the Seventh Annual Convention American Association for Promoting Hygiene and Public Baths, Newark, N. J., May 15, 1918.

life, with its delightful, health giving idealism; this, springing originally from the old chivalric legends of St. George and the Dragon, gave to the Anglo-Saxon many of his noblest traits, and was lost only when the commons and public meeting places were seized and taken from the people by a usurping alien King and his nobility. From this Germanic King's iniquities, the American colonies promptly revolted. Later, England, becoming a manufacturing country, fell more and more under the Teutonic system and exchanged the chivalric St. George for the inartistic and coarse figure of John Bull. Rapidly the rich became richer, and the poor, poorer. It is almost inconceivable that in a land where centered one-third of the world's wealth, over one million of the population were actually, when the war broke out, starving. To over three million were denied the ordinary conveniences of life; baths, both public and private, were to them unknown. Thus, to no country will greater good come out of the war than to England. The changing of the tenure in the House of Lords from a life to a twelve-year term is a portent of the great changes that are coming and of the future in store for the usurping Teutonic nobility which had seized the English people's rights for the past two centuries.

Here we are fortunate in having a relatively free field and a loose rein for the reintroduction of old ideas and the development of new. Moreover, the early settlers in New England brought a strong communal sense which is perhaps more vigorous to-day in the West than in the East. To this sense, the aims and objects of your society should very specially appeal, and public baths, fully equipped for giving hydrotherapy, massage, and exercise, will become as important a part of the community center as are the school and the casino. Medically, hydrotherapy is fully as valuable to the people as is ordinary schooling, and if the one is properly sustained and directed by the state, so should be the other.

What specific support is there for this ground? None greater than the popularity of the New York City baths, established after so many years of laborious effort by your president, that great teacher of hydrotherapy, Simon Baruch! From a modest beginning, the number of baths taken rapidly increased to nearly ten million a year. Equipment follows slowly on education. Let us instruct the general public in the laws of personal hygiene! We are, without doubt, entering upon a new era, which will make for a better and more just national life. The unemployed will be attended to and there will be universal insurance against sickness. Aside from mechanical injuries and general infections, most sickness is now known to be due to what is called focal infection. This is the localization of a focus of bacteria and the distribution from it of living germs, as well as the poisonous products of their lives. Such foci are common in teeth roots, tonsils, sinuses, the appendix, gall-bladder, and the neck of the womb. Modern medicine calls for a careful study of the sick and a most minute search for the focus. After its removal, a matter of great importance to the patient is that elimination of poisons should be accelerated by stimulating the skin. In the experience of many surgeons, post-operative recovery is cut to one-half its usual duration by active hydrotherapy and massage. The beneficial effect of these is enhanced greatly by a change in altitude, there being something remarkable but quite unknown regarding the physiological stimulation resulting from altered barometric pressures.

All these things cost money. Is it Utopian to look for the day to be near at hand when an enlightened municipality will see to it that the poor are offered the same opportunities for health and happiness through hygiene as the rich, and as are everywhere enjoyed by all in our universal and justly renowned public schools?

To recapitulate: We are far behind the ancients in matters of public and private hygiene. The stream of wounded soldiers, soon due, will tax every means of caring for them, and necessitate the development of new and improved therapeutic agencies. Important among these will be baths and hydriatric institutes.

The great war, immersing the world in grief, will so favorably develop our waning altruism, that, like the fabled Phoenix of old, it will rise after the last battle is fought, in primitive strength and beauty to give help to the sick and destitute. Social democracy will favor the growth of the Anglo-Saxon communal idea, and, with schools and playgrounds, will come great baths and health institutes. So that to every citizen alike may come the boon of the healing power of water.

Medicolegal Notes.

Powers of State Board of Health as to Vaccination of Pupils.—Arkansas Acts 1913, p. 351, § 5, gives the state board of health general supervision and control of matters relating to health, requiring it to make a study of the causes and prevention of infectious and communicable diseases, and giving it direction of all matters of quarantine and of all sanitary and quarantine measures for dealing with diseases in the state. Section 6 authorizes it to make all necessary and reasonable rules and regulations of a general nature for the protection of infectious and contagious diseases. Section 28 provides a punishment for violation of the board's rules. The Arkansas Supreme Court holds that under sections 5 and 6 the board was authorized to adopt and promulgate a rule, requiring a certificate of successful or recent vaccination or immunity from smallpox as a condition to attendance upon the schools of the state. The courts of the state will judicially notice such a rule, and it need not be proven. It in no way infringes upon the constitutional right to attend the schools of the state, nor upon the management and control of the schools by school boards or directors. The statute is held to be merely the delegation of the power to determine some fact or state of things upon which the law makes, or intends to make, its own action depend, and hence is not invalid as a delegation of the lawmaking power. It is held that in view of the fact that smallpox was prevalent in the state at the time the rule was not unreasonable and unnecessary even though the school district concerned in this particular case was isolated and smallpox was not prevalent or threatened therein. Every presumption is indulged in favor of the necessity of such a rule, and courts will not interfere with acts of health authorities unless it is apparent that the rule is arbitrary. The rule is not in conflict with the Compulsory Education Act of 1917, requiring every parent, guardian, etc., of children between 7 and 15 years, inclusive, to send them to a public, private, or parochial school, under penalty, as the net result of the acts, when read together, is to enforce vaccination by a penalty only.—State v. Martin, Arkansas Supreme Court, 204 S.W. 622.

Military Medicine.

Diphtheria and Diphtheroid Bacilli in Open Wounds.— In the *Canadian Medical Association Journal* for September, 1918, are published the results of an investigation concerning diphtheria and diphtheroid bacilli in open wounds, conducted by a commission of the Canadian Army Medical Corps, composed of Col. J. G. Adami, Major F. B. Bowman, and Captains P. Adams, A. G. Fleming, C. D. Farquahrson. C. Imrie, and R. M. Janes. The conclusions were as follows: (1) Morphologically and in the early stages, culturally diphtheroid bacilli from wounds are, many of them, indistinguishable from *B. diphtheriæ*. (2) Harmless, non-toxic bacilli may be present in wounds affording cultures possessing the same sugar formula (dextrose, lactose, saccharose, and dextrine) as does the true virulent Klebs-Loeffler bacillus. (3) It is not justifiable, therefore, to make a diagnosis of diphtherial infection of wounds, either from smears alone or from stained preparations and cultural characteristics. The demonstration that the bacilli produce toxins, ectotoxins, the result of inoculation of both cultures, is alone capable of proving the presence of infection by the true virulent *B. diphtheriæ*. (4) By the staining, cultural, and fermentation tests, four cases of apparent diphtherial infection have been detected in a careful bacteriological study of 306 cases of open wounds. By the decisive test of inoculation these are reduced to two. (5) There is a large body of evidence showing that even isolated cases of diphtherial infection of wounds are distinctly uncommon among the wounded overseas, and complete absence of any evidence in Great Britain that these isolated cases have acted as foci for the spread of infection to other wounded men. No evidence of a widespread infection of open wounds by diphtheria bacilli has been discovered in Canadian hospitals in Great Britain. (6) Diphtheroid bacilli of various orders, while not common, are, as might be expected, more frequent in open wounds. There is no evidence that these have exerted deleterious effects. (7) There is a certain amount of evidence that particular species of diphtheroid bacilli characterize particular hospitals.

Red Cross Hospital in Genoa.—The American Red Cross Hospital, founded two months ago at Genoa, has been turned over, with complete equipment and personnel, as a gift to the United States Navy, and will in the future be under the direct control of the Navy. The hospital contains thirty-two beds. Dr. J. C. Clark, U. S. N., is in charge.

Sick and Wounded Men Brought Home.—The War Department announced on November 1 that there were landed in this country during the month of October 4,339 sick and wounded men from the American Expeditionary Forces.

Census of Nurses.—The American Red Cross, at the request of the Government, is making a canvass to bring in the names of any women who are either doing nursing or have been nurses in the past. The census aims to reach not only graduate nurses but those who have taken only undergraduate courses, those who have taken Red Cross courses, those who have been midwives or have had practical experience, and women whose only experience in nursing has been in the home. The object of this record is so that the War Department can release nurses for service in France and still be sure that the civilian population will not be left without nursing resources. Women who have had experience are urged to send their names to the nearest Red Cross chapter or to the offices of the supervisor, which are at 44 East Twenty-third Street, New York. It is said that up to November 1 only about 260 nurses had volunteered for war service in France as a result of the nursing survey now being made by the Atlantic Divsion of the American Red Cross. These women are among the 3,056 in the nation who have answered the recent call of the War Department and the Red Cross.

Influenza Disappearing from Army and Navy.— The War Department reported on October 29 that the influenza epidemic is over in ten naval districts and that it is waning in all other places except Paris Island, South Carolina, and Mare Island, California. The number of new cases of influenza in the army camps is likewise diminishing rapidly. The Surgeon General of the army announces that vaccination against pneumonia is now available for every officer, enlisted man, and civilian employee of the army. The vaccine is being produced in large quantities in the Army Medical School and it is expected to lower materially the number of cases of pneumonia in the army this winter.

Army Acquires More Hospitals.—The War Department announces that hospital facilities have been procured to care for 19,200 additional patients by the Hospital Division of the Medical Corps during the past month, bringing the total facilities outside of the camps and cantonments up to 50,000, or one-third the estimated need of the army for the coming eighteen months. The plan calls for securing 5,000 new beds each month. Wherever possible, hospitals and other institutions already in existence will be utilized. As a part of this plan the Government has taken over North Brother Island and the Riverside Hospital in New York City, the nine buildings in the Exposition Park at Rochester, and the Westchester (N. Y.) Almshouse, which, after alterations are made, will accommodate 2,000 patients. It is estimated that to make all the new buildings accepted ready for army hospital purposes alterations costing approximately $995,000 will have to be made. These will be undertaken at once, and practically all of the newly acquired buildings will be ready for occupancy by January 1, 1919.

Red Cross Reorganized in France.—Owing to the vastly extended military operations of American troops in France a complete reorganization of the work of the American Red Cross in that country has seemed advisable. Instead of the work being divided into two separate branches, one for military and the other for civilian relief, France has been divided into nine zones, with a manager in control of operations in each. Under the reorganization plan Major Homer Folks has been appointed Director of the Department of General Relief, Major Alexander Smith, Director of the Supplies Department; Colonel Fred T. Murphy, Director of the Medical and Surgical De-

partment; Major J. B. A. Fosburg, Director of the Army and Navy Service Department, and Major Alexander Lambert, Director of the Medical Research and Intelligence Department.

Enormous Growth of Red Cross.—The 3,854 chapters of the American Red Cross held their annual meetings throughout the United States on October 23, when a message was read from Henry P. Davison showing the remarkable growth of the organization since June 1, 1917, when a little band of eighteen workers sailed for France. On that date the membership of the organization numbered 486,194. On July 31, 1918, the membership of the organization numbered 20,648,193. Within eighteen months the American people have given $325,000,000. In addition to this sum of money large contributions of materials and supplies of all kinds have been donated and much time has been given by millions of women throughout the country. The announcement is made that during the Christmas season a call will be made for a new enrolment of members.

Deaths in the Service.—Major Alfred Reginald Allen, Infantry, U. S. Army, of Philadelphia, graduate of the University of Pennsylvania in 1898, was killed in action in France during the heavy fighting northwest of Verdun, on September 30, aged 42 years. He was a member of the American Urological Association, twice president of the American Psycho-Pathological Association, president of the Philadelphia Urological Society, a member of the American Association of Pathology and Bacteriology, secretary of the American delegation to the sixteenth International Congress to Budapest, Hungary, in 1909, and to the seventeenth International Congress in London in 1913. Major Allen was lecturer in urological electrotherapeutics, associate lecturer in neurology and in neuropathology in his alma mater. When war was declared against Germany he entered the line rather than the Medical Corps, attended the Infantry School of Arms at Fort Sill, Okla., and was assigned to duty with the Three Hundred and Fourteenth Infantry.

Captain Fred S. Towle, M. C., U. S. Army, of Portsmouth, N. H., lost his life in the fire that destroyed the officers' quarters of the Base Hospital No. 3, at Colonia, N. J., on October 9. He was a graduate of the College of Physicians and Surgeons, New York, in 1893, city physician and chairman of the Board of Health of Portsmouth, Surgeon-General on the staff of Governor George A. Ramsdell in 1897-99, and at the time of his death president of the New Hampshire State Medical Society. He was 55 years of age.

Captain Howard B. Jackson, M. C., U. S. A., of Melrose, Mass., died recently at Fort Oglethorpe, Ga. He was born in 1874 and was graduated from the Harvard Medical School in 1901.

Lieutenant Rushmer Christian Christiansen, M. C., U. S. Navy, died at Mare Island, California, on October 18, of pneumonia. He was born in 1890 and was commissioned in the Navy from Iowa in 1915.

Lieutenant John Joseph McLarney, M. C., U. S. Army, of Ansonia, Conn., a graduate of the University of Maryland Medical School, in 1913, died of pneumonia at Fort Slocum, N. Y., on October 11, aged 29 years.

Captain Victor Moreau Rice, M. C., U. S. Army, of Batavia, N. Y., a graduate of the University of Buffalo, N. Y., in 1904, a Fellow of the American Medical Association, and a specialist in roentgenology, died in General Hospital No. 14, Fort Oglethorpe, Ga., from pneumonia, following influenza, on October 13, aged 38 years.

Lieut. Argo Montague Foster, M. C., U. S. Army, Kaukauna, Wis., a graduate of the University of Michigan, Ann Arbor, in 1910, died in the North Shore Hospital, Chicago, from infection following an operation on the nose, on September 2, aged 33 years.

Capt. Lorenz Burrows, Jr., M. C., U. S. Army, of Buffalo, N. Y., died of pneumonia while on duty at the Buffalo Base Hospital No. 23, on September 17, aged 51 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1889, a Fellow of the American Medical Association and the New York Academy of Medicine. He was ophthalmologist to the Buffalo General Hospital before the outbreak of the war. Captain Burrows served in France during 1917.

Lieut. Arthur Lewis Byerlein, M. C., U. S. Army, died from bronchopneumonia following influenza at the Walter Reed Hospital, Washington, D. C., on October 10, aged 30 years. He was graduated from the University of Illinois in 1910, was in the Government service in the Canal Zone from 1910 to 1916, and was later on duty in the orthopedic department of the Walter Reed Hospital.

Assistant Surgeon Hadley Howard Teter, U. S. Navy, of Cleveland, Ohio, a graduate of the Ohio State University, Columbus, in 1916, aged 27 years, is reported to be one of the missing from the U. S. S. *Tampa*, which was torpedoed in foreign waters on September 26 while escorting a convoy.

Lieut. Pressly Robinson Brown, M. C., U. S. Army, of Sweponville, N. C., a graduate of the North Carolina Medical College, Charlotte, in 1914, is reported in the *Official Bulletin* of July 15 to have been killed in action in France.

Lieut. Morris Finkelberg, M. C., U. S. Army, of Spring Valley, Ill., a graduate of Loyola University, Chicago, in 1908, aged 31 years, was killed in action in France on September 15.

Lieut. Joseph Charles Monnier, M. C., U. S. Army, of Cleveland, Ohio, a graduate of the Western Reserve University, Cleveland, in 1917, died from pneumonia in Washington, D. C., on October 2, aged 28 years.

Lieut. Emil King, M. C., U. S. Army, of Fulda, Minn., who was on duty with the American Expeditionary Forces in France, is reported to have been killed in action about October 7. He was a graduate of the University of Pennsylvania, Philadelphia, in 1893, and was 51 years of age at the time of his death.

Lieut. Irving Jones Pinkus, M. C., U. S. Army, of New York City, a graduate of the University and Bellevue Hospital Medical College in 1914, aged 27 years, is reported to have been killed in action on August 31.

Lieut. Admont Halsey Clark, M. C., U. S. Army, a graduate of Johns Hopkins University, Baltimore, in 1915, assistant professor of pathology in his alma mater, and one of the most promising of the younger pathologists in America, died from

pneumonia, following influenza, in Johns Hopkins Hospital, October 13, aged 30 years.

Lieut. Earle Robinson Achley, M. C., U. S. Army, of Bartow, Fla., a graduate of the Medical College of Ohio, Cincinnati, in 1904, a Fellow of the American Medical Association and the Cincinanti Academy of Medicine, died of pneumonia, following influenza, at Camp Greenleaf, Fort Oglethorpe, Ga., on October 13, aged 44 years.

Lieut. Max Marowitz, M. C., U. S. Army, of Youngstown, Ohio, a graduate of the Chicago College of Medicine and Surgery in 1916, serving with the British Army, died of wounds received while giving first aid to his men, on September 1, aged 23 years.

Lieut. Duncan M. Stone, M. C., U. S. Army, of San Antonio, Texas, a graduate of the University of Tennessee, Nashville, in 1909, died from pneumonia, following influenza, in General Hospital No. 14, Fort Oglethorpe, Ga., on October 13, aged 36 years.

Lieut. Porter Perry Pillans, M. C., U. S. Army, of Orlando, Fla., died in General Hospital No. 14. Fort Oglethorpe, Ga., from pneumonia, following influenza, on October 13, aged 38 years.

Lieut. Waldemar T. Richards, M. C., U. S. Army, of New Orleans, a graduate of Tulane University, La., chief surgeon to the Presbyterian Hospital, New Orleans, and at one time editor of the *Pan-American Medical Journal,* died at his home, from pneumonia following influenza, on October 14, aged 39 years.

Lieut. Harry Paul Martin, M. C., U. S. Army, of Chicago, a graduate of Rush Medical College in 1916, on duty with the Fourteenth Sanitary Train, Two Hundred and Fifty-sixth Field Hospital, died at Camp Custer on October 13 from pneumonia.

Lieut. Edmond I. Monquin, M. C., U. S. Army, of Fair Water, Wis., a graduate of Marquette University, Milwaukee, in 1913, died from pneumonia at General Hospital No. 14 at Fort Oglethorpe, Ga., on October 14, aged 30 years.

Lieutenant Joseph Clarence Balson, M. C., U. S. Army, of Passaic, N. J., a graduate of the University and Bellevue Hospital Medical College, in 1912, died from pneumonia, following influenza, at his home, on October 11, aged 29 years.

Lieut. George Rupp Pretz, M. C., U. S. Army, of Lebanon, Pa., a graduate of Johns Hopkins University, in 1909, died from influenza, while on duty at Syracuse, N. Y., on September 30, aged 38 years.

Lieut. Homer Coulson Parrish, M. C., U. S. Army, of Fort Benton, Mont., a graduate of the University of Illinois, Chicago, in 1908, died in General Hospital No. 14, at Fort Oglethorpe, Ga., on October 14, from pneumonia, aged 46 years.

Lieut. Philip Frank Shaffner, M. C., U. S. Army, a graduate of Rush Medical College, in 1909, died while on duty at Fort Riley, Kan., following an operation for appendicitis, on October 21, aged 33 years.

Lieut. Thomas Riggin Adams, M. C., U. S. Army, of Califon, N. J., a graduate of the Medico Chirurgical College of Philadelphia, in 1915, died of pneumonia, following influenza, while on duty at Camp Lee, Va., on October 4, aged 26 years.

Lieut. Harry Charles McIntosh, M. C., U. S. Army, of St. Paul, a graduate of the Chicago College of Medicine and Surgery, in 1913, died while on duty at Camp Sherman, Chillicothe, Ohio, from influenza, on October 6.

Lieut. Henry Joseph Rowe, M. C., U. S. Army, of Chicago, a graduate of the Northwestern University Medical School, Chicago, in 1913, an interne in the Michael Reese Hospital, died in that institution on October 25, aged 26 years.

Lieut. William Carlyle Kantner, M. C., U. S. Army, of Seattle, a graduate of Wilamette University, Salem, Ore., in 1907, attached to Base Hospital No. 50, died in France from angina pectoris, September 15, aged 33 years.

Lieut. Clarence Hull Dobbs, M. C., U. S. Army, of Jacksonville, Fla., a graduate of the Atlanta (Ga.) College of Physicians and Surgeons, in 1910, died while on duty at Camp Zachary Taylor, Louisville, Ky., on October 6.

Lieut. William Karp, M. C., U. S. Army, of Portsmouth, Va., a graduate of the Medical College, Va., in 1915, died from influenza, at Camp Meade, on October 9, aged 31 years.

Lieut. James David Atkins, M. C., U. S. Army, of Chrighton, Ala., a graduate of the University of Alabama, Mobile, in 1906, died of pneumonia while on duty at Camp Lee, Va., on October 2, aged 38 years.

Lieut. William Buffalow, M. C., U. S. Army, of Jacksonville, Fla., a graduate of Lincoln Memorial University, Knoxville, Tenn., in 1910, died from pneumonia, at his home, on October 8, aged 33 years.

Assistant Surgeon Harry Ellsworth Davey, lieutenant (junior grade), U. S. N. R. F., of Keene, N. H., a graduate of the Boston University School of Medicine, in 1913, died from pneumonia at his home in Keene, on October 15, aged 34 years.

Lieut. Clark Denike Fanton, M. C., U. S. Army, of Riverside, Cal., a graduate of the State University of Iowa, Iowa City, in 1915, died recently in a military camp in California, aged 30 years.

Lieut. Carl Stoeppler, M. C., U. S. Army, of Philadelphia, a graduate of the Medico Chirurgical College of Philadelphia, in 1912, died in the Polyclinic Hospital of Philadelphia, on October 9, aged 36 years.

Capt. William Fielding McIsaac, C. A. M. C., of Antigonish, Nova Scotia, on duty with No. 9 Stationary Hospital in France, is reported to have died from wounds recently.

Capt. M. A. McKechnie, C. A. M. C., of Walkerton, Ont., a graduate of Queens University, Kingston, Ont., in 1917, is reported to have died from wounds recently.

Capt. J. T. Whitworth Boyd, C. A. M. C., of Port Arthur, Ont., a graduate of Queens University, Kingston, Ont., in 1914, is reported to have died from wounds recently.

Major Frederick O. Waage, M. C., U. S. Army, of Red Hill, Pa., died suddenly at Fort Bliss, Texas, on October 30. He was born in 1877, and was a graduate of the University of Pennsylvania Medical School in 1904.

Lieut. Lewis Zion, M. C., U. S. Army, of New York, a graduate of the College of Physicians and Surgeons, New York, in 1915, died of pneumonia at Fort Slocum, N. Y., on October 31, aged 29 years.

New York, November 9, 1918.

THE PAIN AREAS OF CHOLELITHIASIS AND THEIR RELATION TO OTHER AFFECTIONS.

As is known, there are various painful spots which may be detected in cholelithiasis, namely, the cystic, epigastric, pancreatico-cholodohus, costal, phrenic, scapular, vertebral and the area of the right shoulder but biliary lithiasis is not the only disease susceptible of causing pain at these points. This is particularly true of the cystic and epigastric areas. By the term subcostal point, urologists have described a painful renal point which when it is present on the right side is difficult to distinguish from the cystic point. Millon has described a point of pain almost always localized on the right costal edge, between the ninth and tenth cartilages almost under the ribs, in a tonic dilatation of the stomach.

Superficial right-sided pain on pressure under the costal edge and along the relief formed by the rectus muscle has the middle lobe of the liver as its starting point. This sensitiveness of the liver merely signifies that there is active congestion of the organ, but in this same area the angle of the right colon lies outside the cystic point while the kidney is lower down. Inside of the cystic point, under the rectus lie the pylorus and the descending portion of the duodenum, but the pain to which these organs may give rise is deep-seated and circumscribed. It is true that some writers attribute quite a large area to the cystic point and, therefore, cholecystitis, gall-bladder colic, pancreatitis, mucomembranous colitis, and painful renal lesions may give rise to pain here.

The epigastric pain in cholelithiasis may be due to the liver or solar plexus. When of hepatic origin the pain is a symptom of various diseases of the liver and some writers have maintained that it is frequent in gastric and intestinal dyspepsia and in chronic malaria.

There are few painful gastric affections which do not present the maximum point of pain on the oxiphoid-umbilical line or a little to the right of it. This pain corresponds to the solar plexus, or more exactly to the nerve plexus surrounding the celiac trunk. Cancer of the pancreas may give rise to distinct epigastric pain. An epigastric painful spot has been described in pulmonary emphysema which is supposed to be due to the lowered and dilated right ventricle, but it is more apt to be below and to the left of the tip of the sternum.

A localized pain in the pancreatico-choledochus area may be due to lesions of the pancreas and not of the gall-bladder. The costal point may be met with in all congestive processes of the liver and, what is more, Martineau has described a painful costal spot, located exactly at the free end of the twelfth rib in disease of the suprarenal capsule. The scapular and vertebral points, when they are present without any other symptom, may reveal a perihepatic or hepatic painful lesion. Let it also be remarked that the phrenic is a nerve which is often sensitive and, without referring to its frequent neuralgia, numerous are the causes of irritation susceptible of producing an abnormal sensitiveness of this nerve.

PRESENT STATE OF OUR KNOWLEDGE OF THE HYPOPHYSIS.

The hypophysis is a structure of great importance in both physiology and pathology. It is necessary for normal function and probably for existence. Anatomically it is a threefold organ, but functionally it is only twofold. The anterior portion is the more important, in that it is probably indispensable to life. Successful extirpation has almost always led to death, the apparent exceptions having been due to imperfect removal. Alterations in this portion lead to excess or diminution of function, varying with the age of the animal. Hyperfunction causes overdevelopment of the skeleton and hypofunction arrest of the same and infantilism, when occurring in the young, while in the adults a complex condition results in consequence of disturbances in the other endocrine glands. The anterior lobe has functions similar to those of the thyroid but antagonistic to those of the sexual glands. Like the thyroid it enlarges in pregnancy. This phenomenon is believed to be antitoxic in nature, for the anterior lobe enlarges in all intoxications and infections.

However, extracts of anterior lobe subtances have not yet been shown to possess antitoxic powers. Therapeutically they are of some value in infantilism. The medioposterior portion, on the other hand, has not only important functions of a character quite unlike those of the anterior portion but the active physiological principle has an extensive use in therapeutics. It has an action on smooth muscle, regulates diuresis, etc. If ablated, life is not compromised. Hypofunction of this part is of much importance in the pathogenesis of dystrophia adiposogenitalis and adiposis dolorosa. It provokes transient polyuria, augments the tone of the smooth muscle fibers, perhaps causes an increase of carbohydrate tolerance, increases some secretions and diminishes others. The action of the active principle is of the hormone type, *i. e.* through the medium of the blood and without the intermediation of the nerves. Hypophysis extract (posterior lobe) resembles adrenalin in action, but is slower

and less powerful. There is further a hypotensive substance which appears to be present in both portions of the hypophysis but chiefly in the anterior. Hypophysis extract appears to be capable of numerous other activities. Its action on the heart *per se* is equal to that of digitalis. It exerts an activity on the coagulability of the blood, which it may hasten to a greater extent than a number of well known hemostatics. In fact it possesses value as both a local and a general styptic.

Guraldi, whose article on this subject is reviewed in *Malpighi*, and who has summed up the preceding data, adds that the mechanism of hypophysis-polyuria is not yet settled. The latter could be due to elevated blood pressure, to action on the renal artery, or to a specific secretory action on the epithelia of the convoluted tubules. In subjects who do not have elevated blood pressure or arteriosclerosis, hypophysis extract in suitable doses, given over considerable intervals, is of benefit in atony of the heart, uterus, intestine, etc. The active principle is doubtless formed in the medial rather than the posterior portion and passes into the cerebrospinal fluid by way of the infundibulum and third ventricle, then entering the general circulation.

FARCY IN THE FELIDÆ.

THE subject of farcy among the carnivores appears to have greatly interested the Italian pathologists of late, in spite of the manifold diversions of war. In fact the military veterinary laboratories are the ones which are investigating the subject. Some time ago, in the *Annali d'Igiene* Carpano related the results of experiments in inoculating cats from the nasal secretions of a lioness with glanders. The matter was transferred to the nostril of a kitten who fell ill on the sixth and died on the fourteenth day. The *Bacillus mallei* and the ovoid bacterium were both isolated from the nasal secretions. Inoculation of a two-year-old cat, on the contrary, gave a negative reult. A three-month-old kitten was now selected, care being taken to produce no lesion in the nostril. One drop of pus was introduced and the disease became manifest on the fourth day, death resulting on the seventh.

A hypodermic inoculation of a young dog caused only a local abscess. An adult cat after having been placed in the cage with the sick kitten developed the disease and died on the twelfth day. The incubation period was five to six days. Finally another adult cat was successfully inoculated with the blood of the preceding animal.

The experimenters were convinced that the large felidæ were attacked by a mixed infection—acute glanders and a pasteurellosis. The course was almost invariably acute, even hyperacute, so that little time was afforded for lesions to develop. In one case in a lioness in which nodules and ulcers appeared in the skin, the disease had persisted for six weeks. Some lesions were found at autopsy in the intestines and the mesenteric lymph nodes were enlarged.

The fact that these menagerie felidæ develop the disease in captivity speaks for lowered resistance, but the susceptibility of cats shows that members of the cat tribe like those of the horse tribe are predisposed to the infection which passes readily from nose to nose. It is possible, however, that the virus can be swallowed, absorbed through breaches of continuity such as occur in the gastroenteric tract from rough eating habits, and deposited secondarily in the nasal mucosa. The first manifestations are always referred to the digestive tract.

The author has little to say of the pathogeneity of the associated bacterium save that it is known as the *Bacterium felisepticum* and the *Pasteurella felis*. It is regarded as one of a group of organisms which cause a form of hemorrhagic sepsis. Similar mixture of infection has been claimed in human farcy, the streptococcus having been accused in this connection. The hyperacute, septic course, with the occasional supervention of hemorrhagic lesions in the intestine, may be due in part to the activities of the pasteurella.

ACTION OF ADRENALIN ON THE GASTROINTESTINAL TUBE.

THIS subject, according to Binet in *La Presse Médicale* for August 5, is but little known to the average medical man. The experimental basis is as follows: Removal of the adrenals is followed by certain alterations in the gastroenteric tract; adrenalin is known to modify the blood supply, secretion, and motility of this tract; not enough is known concerning the absorption of adrenalin when given by the mouth. In regard to the results of extirpation on this tract, a number of experimenters have seen gastric ulcer develop, especially after bilateral extirpation, when it almost invariably occurs. Ten hours after operation, marked hypotension having appeared, ulcers form with great rapidity. These lesions appear at the localities preferred in the human subject in the clinic—pylorus, prepylorus, and duodenum. The ulcers are round or oval, and measure about 2 cm. in diameter at the most. They stand in a definite relationship with gastric acidity, because sodium carbonate, to a certain extent, prevents their development. Finzi found histological changes in the adrenals in five autopsies on subjects with gastric ulcer.

Recently, authors have attempted to isolate a type of adrenal dyspepsia and a gastroenteric form of adrenal insufficiency. Such conditions must stand in some relationship with the functions controlled by adrenalin—vascularity, secretion, and motility. Adrenalin, when injected hypodermically, causes vasoconstriction in the alimentary canal, and is of value in intestinal hemorrhage on this account; but if the action of the drug is sufficiently pronounced the tension is raised to such a point that hemorrhage may be favored. Despite its vasoconstrictor action the drug is known to stimulate the action of the gastric juice, or rather to increase the secretion of free hydrochloric acid. In regard to motility, the drug appears to activate some por-

tions of the gut and to exert the opposite action on other portions. Thus it appears to cause contraction of the esophagus and to relax the intestine, or portions of it. All of the contradictory finds can be explained by the size of the dose, which produces a given effect. Naturally, this peculiarity renders the subject of dosage, especially by the mouth, a difficult one. If the drug is thrown into the rectum it maintains its toxicity unchanged, but when swallowed it ceases to be toxic. The reason is far from clear, for none of the digestive enzymes interferes in any way with its action. We are forced to believe that passage through the liver detoxicates it, and that when absorbed by the rectum it does not enter that organ.

Cocainism and the War.

The efforts at putting an end to the use of narcotics and stimulants during the present war doubtless are due in part to factors not commonly stated. The noncombatants, in addition to other hardships, are in a constant state of suspense from various causes, one of which is the uncertain fate of the fighting members of the family; and hence the consumption of these substances threatens to spread to classes of the population which would be immune in times of peace. This is no speculative argument, for it seems to have a basis of actual fact in some of the warring countries. In *Il Policlinico* for August 4 is a synthetic review of cocainism by Dragotti. The habit was, of course, spreading before the war, and would have continued to spread had no war developed; but the high tension of modern life has been greatly augmented as a result of war conditions and the conscription of the adult man power has left other classes at the mercy of the drug. Almost daily, says the Italian author, victims are taken to the local hospitals. There is no motivation of pain in the formation of the cocaine habit which usually begins as imitation. Moreover, few form the habit through the therapeutic use of the drug, aside, of course, from proprietary catarrh snuffs, and in Italy the latter cases seem to be rare. In times of peace the cocaine habitués usually belong to certain definite classes of people, and while they number prostitutes and criminal degenerates, they also include physicians and druggists, literary people, and artists. Since it intensifies the joy of existence, there is no class to which cocaine taking may not at times appeal. Nothing is said by the Italian writer of any restrictions on the sale of the drug or difficulty in procuring it; if such measures are in force they plainly are as inoperative as they are in New York City with the Harrison law, the Boyland law, and other restrictions on the practice of medicine in full force, yet impotent to prevent anyone who wants it badly from getting the drug at any time.

Superhealth and Disease.

That men who are most euphoric and have the keenest subjective feeling of health may be already in the grip of some malady is so well known to experienced practitioners that some of the latter come to dread the statements of their clientele as to redundant health. This subjective attitude can be explained at times by the subtle stimulation of disease toxins. We know that protoplasmic poisons are all stimulants in minute doses. But this view seems somewhat narrow to explain all of the phenomena which illustrate the thin partition between redundant health and disease unless we generalize very broadly. The candidate for cancer is often not only the healthiest of subjects but never so abounding in health as when the malady first declares itself. This is an argument in support of the growing theory that cancer is constitutional from the start and that the apparent superhealth is in reality the result of stimulation by protoplasmic poisons of some kind, the result no doubt of metabolic anomalies. Let us consider the arsenic eater as depicted by trustworthy practitioners who have studied him in his native Austrian mountains for many years. He is really a better man by biometric standards than an ordinary citizen. He responds to every criterion for an extra-sound subject, and, what is more, he is not an addict, or, at least, not necessarily one. There is some reason for believing that all the stimulant-poisons when used by subjects who lead an active out-of-door existence tend to show only their good side. Much has been written about the stimulating effects of tuberculous toxins on the quality of literary and artistic output and these men are proverbially optimistic and exhibit a very sane, even if selfish, attitude toward self-preservation, the natural result of their poor physical condition. The consumptive is one exception to the rule that euphoria breeds indifference to personal hygiene. Not all disease-toxins, however, have stimulant properties. Those of lues, at least, have never been credited with anything of the sort, unless in the initial stage of paresis, a purely organic disease, involving the cortex.

Spondylitis Deformans.

The entire June 30 number of the *Svenska Läkaresällskapets Handlingar* is devoted to a monograph on this subject by Kahlmeter. The work contains over 200 pages, and comprises a large number of case histories. Originally there was great confusion concerning the group of maladies which collectively were known as ankylosis of the vertebral column. At the beginning of the present century the subject became more lucid, as it was at last recognized that the Strümpell-Marie-Bechterew disease, which is an ankylosing arthritis of the intervertebral articulations, is radically different from spondylitis deformans. The author labors to show that the latter of these two affections is simply a form of ordinary arthritis deformans, because there is a close agreement not only in the pathological anatomy but in the causal factors. The essential lesion or process is a regressive alteration in the vertebral cartilages. The author strives to follow up the parallel to the utmost. He makes a primary, or idiopathic, and secondary forms. Of the first named he describes there are 11 additional cases with radiograms only, which have not been studied clinically. He is not, at least in the present paper, interested in the secondary form of the disease. Having isolated the idio-

pathic affection, he says of it that it is eminently chronic, that subjectively its evolution is gradual, although it may be acute at times. The latter behavior is seen after traumatism. The disease clinically may be summed up in two words, rigidity and pain. The sense of rigidity is in the most flexible part of the spine—the loins. The pain is determined or aggravated by postures and acts, but even with the subject in complete rest there are spontaneous pains. The worst pain is felt when the patient seeks to rise from a recumbent position, and it is in this act that the rigidity seems most marked. To the eye of the spectator there are two symptoms, deformity and nervous manifestations—muscular atrophies of nervous mechanism; and on investigation, disturbances of sensation and reflex disorders, none, however, being of marked degree. The affection is rare in the young, common in the elderly, increases with advancing years, and is four times more common in men than in women.

News of the Week.

Influenza on the Wane.—Reports from widely separated points throughout the country show that the epidemic of influenza is gradually receding. The bans which have been laid on public gatherings in many cities are being lifted and with few exceptions the situation is improving. A report from Boston, under date of Oct. 30, shows that approximately 11,000 deaths from influenza have occurred in Massachusetts during the two months the disease was prevalent. In New York City the number of new cases of influenza is rapidly decreasing and the order of the Health Department regulating the opening and closing hours of business have been rescinded. Health Commissioner Copeland has issued a statement advising those convalescent from influenza or pneumonia to be examined by a physician within thirty days after the disease has disappeared. This is recommended as a precautionary measure because it is feared that such patients left in a weakened condition may easily fall victims to tuberculosis. Those unable to pay a physician are advised to attend one of the clinics of the Health Department, all the resources of which will be placed at the disposal of such persons. Dr. W. H. Guilfoy, Registrar of Records of the New York Health Department, declares that the statistics of his department show that the epidemic has hit all classes without distinction, the average number of cases among the well-to-do being just as high as among those in the crowded sections of the city. He also calls attention to a peculiarity of the influenza germ in that it appears to find a fertile field for development among the young and the strong, while children and elderly folks are almost immune. He shows that out of 12,484 fatalities in this city, 8792, or 7 per cent occurred among persons between the ages of fifteen and forty-five years of age, and only two per cent among those who were 65 years of age or older.

Influenza in Paris.—Influenza is epidemic in Paris, France, where 2566 deaths were reported for the week ended Oct. 30. This is the greatest total that has been recorded for any week since the epidemic began in that city. Of the 2566 deaths influenza caused 1263 and other diseases of the lungs 515. It is believed that the height of the epidemic has been passed in Paris as the reports for the past few days have shown a decrease in the number of new cases.

Diphtheria in Troy Institution.—There has been an outbreak of diphtheria among the 700 students of the Rensselaer Polytechnic Institute in Troy, N. Y., who are enrolled in the Students' Army Training Corps. The Schick test is being applied to every student and those who are found to be susceptible to the disease are being immunized.

Street Accidents in New York State.—According to the report of the National Highways Protective Association, 106 persons were killed by vehicles in New York State during October. Of these automobiles caused 95 deaths, trolleys 18, and wagons three. In New Jersey automobiles killed 16, trolleys five, and wagons two. Eight persons have been killed at grade crossings during the month.

Dr. Charles H. Chetwood, formerly head of the department of Urology of the New York Polyclinic Medical School and Hospital, has been appointed Consulting Surgeon to the French Hospital.

Dr. Thomas J. Preston, Jr., formerly of Princeton University, has been appointed dean of the New York Homeopathic Medical College and Flower Hospital.

New York Entertains Visiting Surgeons.—A group of distinguished surgeons, who came here from Europe to attend the Clinical Congress of Surgeons which was to have been held in this city Oct. 21-25 and which was abandoned on account of the epidemic of influenza, have been making a tour of other cities of the country. They arrived in New York on Nov. 6 and were entertained at luncheon on that day by the Department of Surgery of Columbia University. After the luncheon addresses were delivered by Col. George E. Gask of London; Major Adrian Poillet of France; Major Pierre Duval of Paris; Colonel Sir Thomas Myles of Dublin; Lieutenant-Colonel Raffaele Bastianelli of Rome; Major George J. Turner, Surgeon to the British Army in Mesopotamia, and Dr. Henry Beclere of Paris. A dinner at Delmonico's was given the visiting surgeons on the evening of Nov. 6 at which time the members of the medical profession at large were given the privilege of meeting the visiting surgeons. After the dinner many of the distinguished foreign visitors spoke, as well as Surgeon General Merritte W. Ireland of the Army, Surgeon General William C. Braisted of the Navy, Dr. Franklin Martin, Colonel George E. Brewer of New York, who has recently returned from service at the front, and others. On Nov. 7, Dr. Charles E. Elsberg entertained the visitors at a luncheon at the Hotel Plaza, after which the military hospitals of the city were visited. In the evening they were entertained at a private dinner given by Dr. Walter B. James, after which they attended the Stated Meeting of the New York Academy of Medicine which was given over to a discussion of "Surgery in the War Zone" by delegates to the American College of Surgeons.

Report of United Hospital Fund.—The Executive Committee of the United Hospital Fund,

which collects and apportions funds among forty-six hospitals of the city, has submitted a report which shows that the war has greatly crippled the hospitals, owing to the large number of doctors and members of the staffs that have gone to the front. The receipts of the United Hospital Fund for the year ended Sept. 30, 1918, were $181,504, a gain over the previous year of $47,924. Notwithstanding this increase, the rising cost of all kinds of medical and surgical supplies and of labor has been greater so that the expenses of the hospitals for the year showed an increase of $1,771,380.16. Thirty-six out of the forty-six hospitals closed the year with deficits. The total number of patients treated during the year who were unable to pay was 151,655, an increase of 15,243.

Obituary Notes.—Dr. Giuseppe Vittorio Sbordone, a graduate of the University of Naples, in 1889, died of pneumonia at his home in New York City, on October 21, aged 57 years.

Dr. Adolph Morgenstern, a graduate of the Long Island College Hospital Medical School in 1906, died at his home in New York on October 7.

Dr. William J. Bedell, a graduate of the University and Bellevue Hospital Medical College, in 1898, died of pneumonia at his home in New York, on October 23, aged 48 years.

Dr. Edward Kenneth Lubin, an interne at Bellevue Hospital, died there of influenza on October 27, aged 23 years. He was graduated from the University and Bellevue Hospital Medical College last June, and recently received a commission as first lieutenant in the Army Medical Corps.

Dr. Hyman R. Wiener of Harrisburgh, Pa., a graduate of the University of Maryland School of Medicine, in 1912, died recently of pneumonia, in a local hospital, aged 29 years.

Correspondence.

ABORTING THE GRIPPE.

To the Editor of the Medical Record:

Sir:—In my brief letter in the Medical Record of October 19, on "The Value of Sodium Bicarbonate for Common Colds," I mentioned the use of phenacetine and soda in "grippe." As this is of such vital importance just now, and as after many years' use of it I have found invariably good results, I cannot refrain from trespassing again on your space, in the cause of humanity. I do this especially because many physicians to whom I have mentioned it do not seem to grasp its importance, and many express a fear from the size of the dose. They often speak of using smaller doses, compounded with other things, but seldom speak of really aborting the trouble, which can surely be done by this means.

I cannot tell just when I began this measure, but for ten or twenty years I have always kept the powders on hand, and used them most satisfactorily during many epidemics of grippe, for myself, in my family, and with my patients and friends, and never in a single instance have I had cause to regret, but have had the unqualified thanks of dozens who realize that the disease was aborted. Only to-day a gentleman from the West spoke incidentally of fearing the grippe, and I said that I would give him some powders which would break it up, if he was threatened, and he instantly asked if they were the same as those which had worked so wonderfully years ago, and several times since. Yesterday a lady said that she had been nursing several in her family, severely ill with it, and felt all the premonitary symptoms herself, and expected to take her turn in bed. I gave her a powder myself, at once, with hot water, and a prescription, with directions to take one every two hours, and one on rising in the morning, and to continue further if needed. I expect to see her in a week and to learn that she "did not have any grippe after all," as so many have remarked under similar circumstances.

In my own family this has occurred time and again, and, with six children and many servants, we have never had any one in bed with it, as I remember. Repeatedly my wife will tell me that some one is coming down with the grippe, and ask, "Shall I give some powders?" I hand out my box, and generally that is the last I hear of it. Only to-night I answered a letter from a patient asking as to the number of doses to be taken.

The plan of treatment, as indicated in the foregoing, is so simple that little more need be said. With the adult I always give ten grains of phenacetine and twenty of bicarbonate of soda. Three weeks ago I gave a child with psoriasis, 13 years of age, seven and a half grains with twenty of soda, every two hours; she had had influenza for a week, with fever, and was a miserable sight. Yesterday, returning for the first time, the mother said, "The powders worked wonders"; she took them that day and the next, and on the following day was brisk and well. I, myself, have recently felt the wonderful bracing up, after a few powders had removed the depression and general aching. It is probably better to keep quiet while under this treatment, and if there is the least heart depression to add a trifle of whisky to the hot water; but I have had any number of patients who have gone about their usual avocation, and I myself have never exercised any precautions.

The powders are placed dry on the tongue and about a third of a tumbler of pretty hot water taken after them. After they have been taken in one or two courses, I often have them continued for a while, one on retiring and on rising, to ward off further trouble. One cannot always clearly explain the rationale of every treatment, and it must be granted that experience is a very considerable factor in medical success. I realize that some will regard me as unduly enthusiastic in thus urging a remedy, but I think that the present epidemic warrants some enthusiasm about a measure which has uniformly yielded such good results over so many years. I hope others will report upon it.

L. Duncan Bulkley, M.D.

531 Madison Avenue, New York.

PROPHYLACTIC VACCINES IN INFLUENZA.

To the Editor of the Medical Record:

Sir:—We are still in the throes of the influenza epidemic and it is unwise to relax any effort in fighting this great foe. On October 30 there were 5349 new cases of influenza and 1026 new cases of pneumonia, a new high record for this disease.

There are two points that need to be emphasized: First, the excellent advice has been given that every person with symptoms indicating a probable onset of the disease go immediately to bed and conserve every ounce of strength in fighting the infection. To this should be added the additional mandate that no one should get up out of bed and stir about until at least five days after the temperature has become normal. Dr. Charles L. Mix, Major, Medical Corps, U. S. A., stationed at Camp Mills, reporting on the epidemic among soldiers, says: "We have reached the conclusion that it is wholly unsafe to send out a patient before he has had at least seven days of normal temperature, and I think that as my experience increases I shall arbitrarily raise my date of discharge to ten days of normal temperature." It is an undeniable fact that the fatal cases have been chiefly in those who have quickly defervesced, and, feeling all right again, have gone back to business or taken up their social obligations only to come down with high fever and pneumonia.

The second point is that prophylactic vaccines have not been insisted upon. It is still being debated as to whether vaccines prevent either influenza or pneumonia; certainly they cannot be expected to "cure" these diseases once they are under way. But this much can be said—vaccines when properly used cannot do harm. It is now agreed that they increase the number of white blood cells, the scavengers which destroy great numbers of bacteria. In influenza the number of white blood cells are diminished by the disease, thus destroying an important line of defense against the invader. Vaccines stimulate the formation of new white blood cells, and thus increase the body resistance to infection. They also increase the appetite and favor quiet, restful sleep. Many of the hospitals, such as the Manhattan Eye, Ear and Throat, have immunized the entire staff, and while an occasional case of influenza has developed thereafter, the mortality has been practically nil among those doctors and nurses who have submitted to this harmless inoculation of dead bacteria.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE COMING MINISTRY OF HEALTH—CHILD WELFARE AND PUBLIC RESPONSIBILITY—THE WAR AND LUNACY—URBAN INSANITATION.

LONDON, October 10, 1918.

FROM the expressions of Dr. Christopher Addison, the Minister of Reconstruction, at a recent meeting of the medical profession, there can be no doubt that the institution of a Ministry of Health will form part of the Government program in the next session of the House of Commons. The reasons for the establishment of a Ministry of Health as one of the principal Departments of State have been detailed in these columns on several occasions, and a summary of those reasons shows that the movement is not a revolutionary one but a true development—a development in which that part of public medicine which is good will be extended, and that part which is redundant or reactionary will cease to exist. On the face of it the bill, when it is read, will be an assortment under one Government department of duties which at the present moment are discharged by six or seven departments, with consequent waste of time, overlapping of energy, and aggravated expense. But when the medical activities of such various and varying bodies as the Local Government Board, the Board of Education, the Home Office, the Foreign Office, the Privy Council, and others are considered, it will be seen that there should be no great difficulty in centralizing them, if a proper coordinating authority be set up. The reasons for wide, anomalous distribution of public medical duties have disappeared, so that none of the existing Government Departments want to be confirmed in their medical work, though none want to hand it over without knowing that the scientific responsibilities will be duly discharged by a new central bureau. Such difficulties as lie in the way of the the Government in promoting the contemplated bill can only be met by providing in the bill for a strong Medical Consultative Council, composed of medical men who are truly representative of professional interests, this not out of tenderness for doctors, but out of genuine feeling, that good public servants will only be obtained in response to proper conditions of service. That the Medical Consultative Committee should be properly chosen is a more important proviso than the one on which so much stress is often laid that the Minister himself should be a doctor. There is certainly no reason why the Minister should not be a doctor, and there would be considerable fitness in his possession of medical titles, but a clear-headed public worker, willing to trust a competent Medical Consultative Council would be a far better protagonist of the cause of national health than the wisest of medical men could be, while hampered by having to defer in principle or detail to assessors with no medical equipment. The knowledge from the mouth of the Minister of Reconstruction, himself quite probably the first "Minister of National Health," that by the new bill no institution of a wholesale state service is intended, has been a great relief to many leaders of medical thought, for the conditions of medical practice in this country seem hardly ready for such a revolution.

In England the mother has not yet got an efficient medical service at her disposal for herself and her children, and the provision of this is one of the after-war problems which the citizens have to settle, and the citizens of London should be in the front of the movement, having regard to the population and aggregate wealth of the community.

We need a system by which there will be secured a family doctor for each family. The relations of the family doctor to the special institutions such as School Clinics, Tuberculosis Dispensaries, Maternity and Child Welfare Centers, and Venereal Disease Clinics will have to be determined. The family doctor must be linked up with the consulting surgeons and physicians, and the hospitals, convalescent homes, midwives, district nurses, and mothers' helps, so that his patients may have the benefits of these services in time of need. More lying-in hospitals, more children's hospitals, and open-air schools are required. Especially do we need more hospitals for crippled children. Besides this, arrangements must be made for dentists to look after

the teeth of the children. This has been done to some extent in the case of children of school age by School Clinics, and the system will have to be extended. As I have said above, the new bill for a Ministry of Health does not purport to institute any State system of medical practice, whereby every doctor would become a regimented officer in a salaried service. Nor must it disturb the voluntary hospital system, but that system, if it is to be unmolested, must set its own house in order.

The reform of out-patient departments in these institutions is urgently needed. Serious cases are at present swamped by cases which ought never to be sent there. "Mothers who take their children to out-patient departments are frequently required to spend the whole day in the waiting-room, to the great detriment of their homes." These were the words employed by Dr. Harold Scurfield in a recent lecture delivered in London on "After War Problems," and there is no doubt that in many directions in the county the children could be given a better chance. County Councils and Sanitary Authorities are now required to establish Maternity and Child Welfare Centers, and the representatives of the citizens must see that these are as efficient as possible. There should be provided advice and hospital treatment if required for expectant mothers; medical attendance under certain circumstances, and hospital treatment, if required, during confinement; and advice and hospital treatment, if required, for both mother and baby after confinement, the advice to be continued, in the case of the baby, up to the school entrance age. As regards hospital treatment, the usual way is for the Sanitary Authority which establishes the center to make arrangements with the existing hospitals, but some Sanitary Authorities may find it advisable to establish lying-in hospitals and infant hospitals. At present we have medical supervision of children from birth up to the age at which they leave school, but no provision has been made for the gap between leaving school and the age of sixteen, when those who go to work come under the scheme of the Insurance Act. This is an anomaly which is always, and rightly, being used to prove the necessity for a central scheme of National Health, so that the general care of the individual should receive one central supervision.

The annual report of the General Board of Control (Lunacy Board) of Scotland gives statistics which show that there has been a steadily progressing decrease since the outbreak of war of lunacy in Scotland, and a similar reading can be put upon the lunacy statistics for the past twelve months of other divisions of the kingdom. The decline in the admission rate to public asylums of pauper lunatics is the salient point. It is true that this decline had begun to take place before the commencement of war, owing perhaps to the general prosperity of the country, removing from wage earners much of the stress of poverty and the anxiety of non-employment. But since the drastic regulations with regard to alcohol have begun to tell on the morale of the population, the decrease of pauper lunatics has been marked. The death-rate among this class has slightly increased by comparison with the figures of last year.

And just as war conditions have been accompanied by an actual decline in the lunacy rates among paupers, so, on the whole, the profoundly disturbed and disturbing social conditions of war have not led in England to the amount of trade difficulties which might be gathered from newspaper accounts of strikes in various directions. The relations between employer and employed, whether we have to deal with State Departments like the Police, with great corporations not under Government aegis like railways, or with private companies like those which exploit the coal mines, have required readjustment, and probably will require it in a further measure. But the set-backs to the prosperity of the country or to the prosecution of the war by the occurrence of these trade disputes have not been serious, although the German journals have chosen to think otherwise. The position arising in one or two lunatic asylums out of the strike of attendants and nurses opened the eyes of the public to the mischief that would inevitably follow if in certain directions whole social services were disbanded while questions of payment were threshed out, and many lay papers drew a moral from the imagined horrors of a medical strike, and in so doing awoke the public to the fact that strikes of a particular nature are wholly unjustifiable. One such strike having a medical side prevailed in the important and central district of London, called Holborn, this week, coming to a conclusion as abruptly as it had started. For several days the public service of the Holborn district having the care of the condition of the streets was suspended; streets were not swept and were not watered, gullies were not flushed, *débris* of all kinds—manure, paper, tins, boxes, tobacco ash, and the like—collected mainly in the small side streets. The manure, indeed, was largely to be found in a thick paste on these side streets, because the major thoroughfares, being used for motor traffic, horse traffic tended to take the minor routes. This disgusting condition of affairs was maintained for about a week, and the interesting point about it is that the public health of the community, as far as the figures of the municipal health office go, showed no immediate depreciation. There was no rise in such disorders as infantile diarrhea, and it is possible that the presence of rain and absence of wind, by preventing the dissemination of dust, prevented also catarrhal conditions of eyes, nose, mouth, and throat.

As, apparently, there was no "doctor's bill to pay," the public will conclude that "all is well that ends well," but the medical view is something very different. No one supposes that a week's dirt will undo all the advantages to be derived from many years of organized cleanliness; the danger is lest the public, seeing no immediate harm to result from a dirty environment, should tend to estimate medical recommendations with regard to public sanitation as being based on fussiness rather than on fact. To such people the public health statistics of important cities, not only in the East and in Russia, in the Balkans and in Spain, but even in parts of Italy and parts of Ireland, should prove a salutary lesson. The dirt of the day does not matter—it can be shifted. The dirt of years becomes an insanitary bequest to future generations, and its evil is hard to combat.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

THE AMERICAN IS COMING INTO HIS OWN—ANIMAL EXTRACTS FOR TREATING WOUNDS—THE FRIENDS HOSPITAL BOMBED—THE OPINION OF SOME NOTABLE GERMANS—THE PARIS WOMAN'S RELIEF CORPS.

PARIS, September 17, 1918.

THE appreciation of what America and her sons are doing finds expression in every place and class in extravagant praise, which is all the more gratifying because of the genuine ring of earnestness and truth that is perfectly apparent.

War correspondents at the front get hardened and callous and rarely deal in florid praise, and I think no more comprehensive idea can be conveyed of what I say than to quote a paragraph from a war correspondent of one of England's great dailies: "As specimens of physical fitness, these farmers, lumbermen and mechanics, many of whom have German names, compare with the Australians, and there are no finer. Never a moan from a wounded man have I heard in the advanced dressing stations. Every man, however badly wounded, has had a smile for a joke and a face that betrayed satisfaction in a task well done."

Professor Charles Richet presented last Monday afternoon, at the Academy of Sciences, a communication from Dr. Serge Voronoff and Mme. Evelyn Bostwick on their new treatment of war wounds. After a great number of experiments on animals in the Laboratory of Experimental Surgery at the Collège de France, they have succeeded in healing in a few days deep wounds which normally require months. Dr. Carrel of the Rockefeller Institute had, before the war, indicated the accelerative properties of the thyroid gland. Dr. Voronoff and Mme. Bostwick have found from various experiments that there is in the organism a gland that disperses throughout the body secretions which are infinitely stronger. This gland is obtained by the castration of a young ram. It is known that this organ produces considerable vital energy. Animals on whom the operation is performed become fat and apathetic. It is that organ that Dr. Voronoff and Mme. Bostwick have utilized with marvelous results.

Large and deep wounds treated by their process, which consists in spreading the pulp of these glands in the wounds, have healed with a rapidity that had never been observed before. Long months of unnecessary suffering have been avoided for soldiers, who have the joy of seeing their wounds heal in a few days. That this method is successful is shown by the fact that Dr. Carrel has called upon Dr. Voronoff and Mme. Bostwick to apply their method at his hospital at Noisiel.

After having passed safely through months of shelling from both land and sea, and bombing from the sky, the headquarters at ——— of the Friends' Ambulance Unit, an institution the American Red Cross has been assisting, has been almost completely wiped out by bombs from German avions. Two of the workers were killed and four injured. The casualty list was small, as most of the personnel were in an "abri." The headquarters of the Friends' Ambulance Unit was in the Hotel ———, which was built in two parts, one more recent than the other. The new part was destroyed. Two bombs fell in the courtyard back of the building, blowing out the whole first story, causing the structure to collapse.

Belgian and French residents in Switzerland (many of whom are liberated prisoners of war) have been struck by a startling German recognition of France's ultimate claims on Germany for the invasion and wholesale destruction of northern France. Hitherto, the general opinion has been that, on the day of peace, France would be unqualified to put up special claims against the invasion of her northern departments, because she is an ordinary belligerent power and comes under the provisions of the Hague Conventions, which proclaim legitimate the levying of war contributions, commandeering of food, etc., by an invader in a country not enjoying the privilege of neutrality as is the case with Belgium. The *Freie Zeitung*, which is published in Switzerland by the few notable Germans whom the crimes of their Fatherland have disgusted and revolted, has, however, just published the following view: "The French northern departments were not reached by the German armies in direct and loyal fight, but only thanks to the violation of the neutral Belgian territory which, by international agreement, adhered to by the King of Prussia himself, was to remain a perpetual and impassable barrier between France and Germany. Therefore, on the conclusion of peace, France will be absolutely justified in claiming that the invasion of her northern provinces does not come under the rules of the Hague Conventions and should be compensated for as amply as the violation and occupation of neutral Belgium." This contention, new though it be, appears quite sound in law and in fact; and the French will be all the more entitled to act by it and enforce its consequences, as it is suggested by subjects of the belligerent enemy and invader.

Though the "Women's War Relief Corps" has been amalgamated with the Red Cross organization proper and no longer exists as a separate organization, the service of the corps remains as before, with additional duties, though it has dropped its name of "The American Women's War Relief Corps" and has become the Women's Division of the Bureau of Personnel of the American Red Cross. Its duties consist in finding quarters for all the Red Cross women who arrive from America. The women of the committee meet them at the boats and the stations upon their arrival in France and find "pensions" or hotels for them and arrange every necessary accommodation for them. All uniforms are applied for through this bureau and tailors are assigned to those who demand a certain class of uniform. The bureau, further, serves as a general information bureau for all women engaged in war relief work in France. The most important part of this division is, perhaps, its women's employment bureau, which has recently been inaugurated. Positions are found whenever possible for all who are in need through losses caused by the war.

Chancroid of the Vagina.—Courtade reports two cases of this rather rare localization; this infrequency may be only apparent, for unless the speculum is used in routine work one can never be certain of their absence.—*Annales des Maladies Vénériennes.*

5. The Use of Heat and Radium in the Treatment of Cancer of the Jaws and Cheeks.—G. B. New reports the results obtained in 21 inoperable cases of cancer of the jaws and cheek by treatment with the cautery and radium at the Mayo clinic in 1917. In most cases, epitheliomas occurred in the fifth decade; two patients were between 31 and 40 years of age, four between 41 and 50, twelve between 51 and 60, and three between 61 and 70. Nineteen were men and two were women. The exact length of time the growth had been present could not be determined; patients had noticed it for periods of from two weeks to four years. Tumor was on the lower jaw in two, on the lower jaw and cheek in seven, on the upper jaw in two, on the upper jaw and cheek in seven, and on the cheek in three cases. Five of the 21 cases had already been operated on. In seven cases, epithelioma was associated with a leukoplakia, and in one instance the tumor developed on a pathologic fracture of a bone cyst of the jaw. All patients were treated by the slow heat cautery with soldering irons, radium being also used. New states that although the decision as to surgical intervention in cases of cancer of the jaw or cheek without glandular involvement must depend on individual judgment, in questionable cases the patient should be given the chance afforded by operation. The technic of the operation is as follows: After the patient is anesthetized with ether, a mouth gag is inserted opposite the affected side. The tongue is drawn to one side out of the way, by the aid of a stomach clicker. The water-cooled speculum is inserted, and all the teeth in the area involved, or those that prevent good exposure of the growth are removed. If it is possible, the entire growth is excised from the jaw or cheek with a knife cautery, and the base is cauterized with soldering irons. If this is not possible, the irons are inserted into the tumor. The water-cooled speculum prevents the burning of the lips or cheeks except in the area being treated, and it affords good exposure. A wooden tongue depressor holds the tongue out of the way and prevents it from being burned. The cautery should be used longer than seems really necessary; at least for from twenty to forty-five minutes. If the growth is in the upper jaw and involves the antrum, the soldering irons are carried up into the antrum and the entire growth is gradually burned away. In case of hemorrhage following cauterization and not readily controlled by packing, ligation of the external carotid with the lingual and facial branches is recommended. Radium is applied about two weeks after cauterization, directly into the open area, from which the slough will have cleared off. The radium is directed into the ulcerating area in lead applicators, using a 50 or 100 mg. tube within a silver tube, for from 15 to 20 hours, without screening. If the cheek is involved, radium is applied, with screening, externally over the cheek; and if the growth has involved the antrum, the radium is placed in the antrum and packed there with petrolatum gauze. In a month to six weeks, large pieces of sequestrum usually come away from the jaw. Further treatment is given in a month and repeated as required. In case of recurrence, a second cauterization is done, and this is followed by radium. As a rule epithelioma of the jaw does not metastasize early, unless there is considerable involvement of the cheek. In such case the submental and submaxillary glands on the affected side should be removed. *Results:* Twenty out of the twenty-one patients have been traced. Twelve have had no recurrence locally or in the glands for from six to eighteen months. One patient, who was operated on before going to the Mayo clinic, has a hopeless recurrence. Two patients died of cancer. New points out that the end results in this series cannot be foreseen, but he believes that much more is being accomplished in the treatment of such cases by the addition of radium than was formerly possible.

1. An Address (Part of) on Sensory Changes in the Diagnosis of Trench Fever. Given Before a Base Medical Society in France.—Major D. W. Carmalt Jones refers to the clinical investigations conducted by Sir James Mackenzie, Dr. Henry Head, and others on the association of inflammation of viscera with areas of increased sensibility of the skin. Some work on the lines laid down by these observers has been done at a Base Hospital in France, and records of 500 consecutive examinations are now available. The work of Gaskell made it possible to construct a working hypothesis, based on the principle that every segment receives an afferent nerve from a viscus, and if the viscus is inflamed the skin area connected with the same segment becomes hyperalgesic. Carmalt Jones describes

in detail the procedure followed; a series of light pinpricks (with a wooden match finely pointed) is applied to the skin along a line which cuts across a number of segmental areas, for instance, from the clavicle to Poupart's ligament. The patient will be seen to flinch when the pricks pass from a normal to a hyperalgesic area; the spot where the flinch occurs is marked with a skin pencil and the experiment repeated from below upward and the skin marked again. The series of 500 included cases of various kinds of fevers, diseases of the circulatory, respiratory, alimentary and genitourinary systems. It was found that of the 130 cases of "fever" of various kinds, trench fever and malaria were commonly associated with hyperalgesia of three definite groups of segments which do not correspnod with those belonging to any of the viscera noted in the series. These areas were: the eighth cervical and first dorsal, the seventh dorsal, and the first, second, third, fourth and fifth lumbar. This is the "full trench fever distribution" and it was noted, more or less completely, in nearly every case clinically diagnosed as trench fever. Of 18 cases of malaria examined, 16 showed precisely similar areas to those found in trench fever. It is suggested, therefore, that hyperalgesia of these particular segments is diagnostic of a group of disease consisting of malaria and trench fever, and it is remarkable that one of them is mosquito-borne and the other louseborne; that both appear to be protozoal, with a definite cycle of development, as shown by periodicity of the febrile attacks; that both appear to lie dormant for considerable periods within the body; and that both are associated with enlargement of the spleen It is possible that the eighth cervical and first dorsal may indicate an affection of the thyroid gland; and the seventh dorsal may indicate the spleen. The significance of a lumbar hyperalgesia as yet is unexplained. Major Carmalt Jones points out the diagnostic value of such hyperalgesic areas in visceral lesions in general. In trench fever he believes hyperalgesia or the areas indicated to be diagnostic, when malaria can be excluded. He suggests also that afebrile cases of other disorders, such as D.H.A. and debility, which show the same changes, may be suffering from a chronic form of the same infection. He points out that among 100 cases of D. A. H. examined at a "heart center" in France, who showed positive changes in sensibility, 67 gave evidence pointing to trench fever alone and of 33 that had signs of a true heart lesion, 22 also showed signs of trench fever. This would mean that trench fever constitutes a serious source of invaliding. In any case, the question is worthy of further investigation.

6. Transfusion of Blood in War Surgery: Some Indications and Results, and Description of New Modified Direct Method.—Major S R. Harrison describes a modified direct method of blood transfusion, by which the blood is conveyed from an artery of the donor to a vein of the recipient in such a way that the operator can observe the flow and knows immediately if the flow ceases or any clotting takes place. The apparatus is simply made. It consists of a Y-tube, two limbs of which are shortened, and two glass cannulæ. The cannulæ are connected to the short limbs of the tube by sterilized rubber tubing; the third limb is connected with a reservoir of saline 0.8 per cent. or sodium citrate 3.8 per cent. by tubing about 5 feet long, which has a clip on it. All rubber connections are conveniently tied with silk. The length of the instrument—that is, the distance the blood must flow through the tube—is about 6 inches. The Y-tube and cannulæ are waxed after sterilization and joined up in position with sterilized rubber tubing. The long limb of the tube is connected to the reservoir of sodium citrate solution and the apparatus is ready for use. The donor's left radial artery is usually taken (unless he is left-handed), the distance between artery and the selected vein in the recipient is roughly measured off with instrument, and the two arms secured in position with adhesive. Two operators are necessary: one to prepare the artery and one to prepare the vein. The skin over the proposed wound is sterilized with 1-20 carbolic, which also acts as an anesthetic. The radial artery 1½ inches above wrist is dissected out through an inch incision, tied off distally with fine silk, a second loop of which is passed under the artery and used later to tie in the cannula. The artery is now opened with a Graefe's knife from above downward and outward, leaving a V-shaped tongue. Pressure in the meantime is applied above the wound to prevent loss of blood. The vein is prepared in the same way. The clip on the tubing leading to the reservoir is now opened, and the apparatus filled with citrate. The artery cannula is now tied into artery and blood allowed to flow until it reaches the tip of vein cannula, when pressure is again applied to artery. The vein cannula is then tied into vein and all pressure taken off artery. The blood can now easily be seen flowing through the Y-tube at the junction of the short and and long limbs where the clean solution of citrate comes in contact with the blood. This can be more easily demonstrated by occasionally opening the clip on the tube to reservoir, which is suspended about 3 feet above the patient, when the clear solution is seen passing quickly into the vein cannula. This is even more pronounced if pressure is applied to the artery. At the termination of the operation the cannulæ are withdrawn after pressure has been applied above each wound, both vessels ligated, and skin sutured. The author states that he has not seen any untoward results from tying off the radial artery. He points out, however, that care must be taken not to cut branches of the radial nerve. From a rough calculation made by running the blood from the radial into a dish containing citrate and subsequently transfusing the mixture, he estimates the amount of blood which passes through the apparatus as 750 c.cm. in five minutes. He has never known clotting to take place, yet he does not consider that the method described has many advantages over some of the indirect methods for general use. In war surgery, Harrison considers that whenever possible "whole" blood should be used, as all the constituents of the blood are necessary, especially in septic and septicemic cases; that a preliminary agglutination test should always be carried out, except when the groups of donor and recipient are known; and that the "Dakin container" direct method is the most simple and efficient method for general use, as the apparatus is easily made or obtainable, the required amount of blood can be given at one filling, and little assistance is required, also whole warm, unadulterated blood, with little chance of infection, is quickly transferred from one patient to another. He adds that, of course, the method selected must necessarily vary with circumstances.

3. Pulmonary Fat Embolism and Its Relation to Traumatic Shock.—Captain George E. Sutton points out that a number of cases of so-called shock arrive at a casualty clearing station showing the following features: cyanosis, small pulse, breathing sometimes labored and increased in rate, cold extremities, delirium of varying degree. Such cases respond little to measures of resuscitation and post-mortem examination invariably reveals pulmonary fat emboli which can be demonstrated grossly. Captain Sutton believes that among fatalities the percentage of such cases is at least ten, and would be found to be higher if sections of lung tissue were stained for fat in all cases. Fat emboli have been found in single and multiple compound fracture of long bones, fracture of skull with destruction of brain tissue, fracture of ribs; in penetrating wounds of the abdomen with maceration of omentum and large wounds of buttock and trunk; and in wounds penetrating the abdomen, with laceration of the liver. In cases of fracture of

long bones where immobility was not complete, symptoms resembling shock were invariably present. In eight fatal cases of profound shock, Sutton examined the lung tissue and found pulmonary fat embolism in six. The work of Warthin, Gauss and Bissell has demonstrated the relation of pulmonary fat embolism to shock, and Sutton points out that if unsuccessful cases of shock are due to acidosis—a prominent opinion to-day—in pulmonary fat embolism all the factors are present to produce this acidosis, that is the physical and chemical properties of lipemic blood are such that acidosis cannot be avoided. He concludes that pulmonary fat embolism is much more frequent in the war zone than was formerly thought; that a reasonably accurate diagnosis of pulmonary embolism can be made; that such cases do not respond readily to measures of resuscitation; and, finally, that the ultimate cause of death in pulmonary fat embolism and shock may be the same—namely, acidosis. The prophylactic treatment consists in fixation of fractures with extension where possible; early and efficient surgical interference for fractures; careful and complete hemostasis at operation on wounds involving fatty tissue, and *particularly the ligation of the non-bleeding proximal ends of veins as well as the bleeding distal ends.* Active treatment is only symptomatic. Small amounts of sodium bicarbonate (2 per cent.) are helpful, the administration to be regulated by the condition of the right heart. Transfusion of blood in small amounts may be useful.

Berliner klinische Wochenschrift.

August 26, 1918.

Diathermy and Its Limits of Efficacity.—E. Tobias, after offering some recommendations of a technical kind, endeavors to sum up the indications and contraindications of diathermic treatment. The preservation of the sensibility is essential and overlooking this fact may be disastrous in the treatment of locomotor ataxia, for example. Constipation of spasmodic origin is favorably influenced by this treatment whose principle resides in the application of heat in the depths of the organism. A sedation of pain ensues as well as stimulation of the local metabolism of the tissues. Muscular and joint diseases are among the most favorable indications for diathermy, after which come certain nervous affections (among which tabetic paroxysms), the neuriticles and neuralgias, with the exception of that of the trijeminus which may be exasperated by the treatment. The virtue of the hyperemic action can be used in the treatment of wounds of warfare, etc. Among the internal organs treated by diathermy at the present time may be mentioned angina pectoris, ischemia from vascular spasm (intermittent claudination), chronic bronchitis, asthma, emphysema (stimulation of the expectoration). The effects on hepatic or nephritic colic are not distinct. Genital affections are being more and more treated by diathermy. It is likewise applicable in the domain of cutaneous diseases (lupus). As essential contraindications the writer mentions the tendency to local congestion and suppurative processes.

Operative Treatment of Urethral Fistulæ and Hypospadias from Bullets.—C. Hirschmann offers the following conclusions: (1) Urethral fistulæ often close spontaneously; (2) when the fistula assumes a labiated aspect, an operation is required; (3) large fistulæ are cured by excision and suture of the urethra with a cutaneous plastic operation or a venous graft; (4) smaller fistulæ may be sutured after freshening the borders; (5) temporary deviation of the urine by a suprapubic opening is to be recommended; (6) avoid the catheter *à demeure* in operations on the penis; (7) hypospadias is closed by a cutaneous flap.

Münchener medizinische Wochenschrift.

August 20, 1918.

The Condition of the Blood in "Edema Disease."—W. H. Jansen states that this affection occurs in conditions of chronic inanition. The writer has observed a marked diminution of both the white and red corpuscles without signs of pernicious anemia. The writer considers this decrease not due to an hydremia related to the edema, but rather as the manifestation of a state of general cachexia. The globular index is usually increased, this being due to the predominance of old globules resulting from the want of sufficient renovation of the blood. The coagulability is usually accelerated. The point of congelation is normal (—0.55° to 0.56°). The tenor of the serum in albumin is lowered (down to 4 per cent., normal = 6.5 to 8.5 per cent.). The proportion of sugar is usually lowered, and the same applies to the lipoids and calcium. The writer attributes this calcic insufficiency to an exaggerated permeability of the capillaries which is made evident by the edemas to which the disease owes its name. On the other hand, the quantity of chlorides does not present any fixed variation, the residual nitrogen and uric acid are present in normal amounts.

The Therapeutics of Protein Bodies.—A. Wolff-Eisner discusses the question of the priority of the discovery of anaphylactic phenomena, claiming, in spite of absolute proof to the contrary, that he and not Charles Richet of Paris is the discoverer.

The Accuracy of Wassermann's Reaction.—K. Zieler concludes that there is necessity to render the reaction more sensitive, for example by employing Kaup's technique, which consists in using graduated doses of the compliment. On the other hand, the sensibilization of the method implies in itself a greater uncertitude in the results, the clinical findings retaining all their rights in doubtful or slightly positive cases.

Deutsche medizinische Wochenschrift.

August 22, 1918.

Regeneration of Tissues in Man.—A. Bier continues the series of his researches on the regeneration of various tissues. That of the muscles has, up to the present, been considered nil. Bier's experiments would seem to show that so negative a conclusion is not justified. He believes, on the contrary, that the presence of a favorable culture medium such as the sero-lymphatic exudate allows the muscle cells to bud, grow, and partially reconstruct the muscle destroyed. The writer has observed this process in two cases of amputation of carcinomatous breasts, comprising the greater part of the thoracic muscles. In one of the cases the muscular neoformation was only simulated by a cicatricial band, but in the second case Bier considers regeneration as certain because the contractile function of the muscles returned, likewise electric excitability. This regeneration was preceded by the formation of a lymphatic exudate over the area of removed muscle. Other cases recorded by Bier gave negative results, but on the other hand, he maintains that he has seen regeneration of the vastus externus muscle in a child in whom he removed a cavernous angioma in this muscle.

The Etiology of the Grippe.—H. Selter in the first place tries to show that Pfeiffer's bacillus is not the specific agent of the present epidemic. Having experimented on himself and his assistant, he came to the conclusion that the agent of the so-called "Spanish grippe" is a filtrable virus which cannot be detected microscopically.

Wiener medizinische Wochenschrift.

August 24, 1918.

The Control of Epidemics in the Army of the Isonzo.—K. Russ exposes the general plan of sanitation barriers instituted to oppose the spread of various infectious diseases. The data, useful both for prophylaxis and statistics, which are to be collected by a special commission appointed for this purpose, are essential. Bacteriological laboratories should be stationed as near as possible to the fighting line in order to quickly assure the elimination of doubtful cases, as well as for a direct superintendence of the trenches by specialists in hygiene. Next come two parallel lines of laboratories located in the other formations, comprising from two to four units. The number of bacteriological examinations done by these various centers is in the mean about 1100 a day. Besides the above units there are central stations for the examination of foodstuffs, centers for Wassermann's reaction and for the control of malaria. The latter possess all the necessary apparatus for the examination of mosquitoes, diagnostic researches and treatment. The hospitals should each have from 250 to 300 beds

near the firing line, rather than large base hospitals some distance off. The transport of men recognized sick should be done within a few hours. The care of the sick and convalescents is favored by the nature of the soil on which the hospital stands. The writer also describes sanitary trains, quarantine measures, movable apparatus for disinfection, etc.

La Riforma Medica.

July 6, 1918.

Three Day Fever.—Gabbi traces this affection back to 1804, at which period an English surgeon, Pym, first mentions it as an affection of the Mediterranean basin. No very important account of the disease appears before 1874-5 when Cicoli and others mention it as occurring in Dalmatia. It was described as a benign fever of brief duration, peculiar to the summer months. About 30 years ago it attracted the attention of Italian military surgeons and has retained it ever since. In addition to the countries mentioned—Dalmatia and parts of Italy—the malady is known to occur in Greece and Switzerland and in the Balkans, but is not a European malady in the ordinary meaning of the term—that is, it is native to Africa and India but exotic in Europe. In recent years its incidence in Southern Europe has been better understood. Thus in 1909-10 an epidemic, the first (?) on record, occurred in Messina and the coast of Calabria. Since that period it has been recognized in many localities in Italy and Sicily and the author has been able to trace all of these cases to this epidemic. It was not difficult to show that in all likelihood Messina in turn was infected from Dalmatia. Since 1909 it has been domesticated in many localities in Italy so that outbreaks occur readily every summer. Whether infected men or infected phlebotomus flies carry the disease about is not yet known. The rôle of this fly in the transmission of the disease was not known until about 10 years ago, when an official investigation by the Austrian government made this plain, as far at least as an epidemic in Herzegovina was concerned. In speaking of these recent epidemics in Italy it should not be forgotten that earlier ones are on record. The affection was epidemic, for example, in Bologna in 1896. The chronology of the disease is somewhat confusing. A distinction must of course be made and upheld between recent importations and old endemic foci.

La Presse Médicale.

August 1, 1918.

Streptococcus Wounds.—Plisson, Ramond, and Pernet attempt a clinical description of streptococcus wounds, which they style a new entity. They have made a study of 67 cases in which the bacteriologic finds were constant—chains of gram-staining cocci. There are, however, numerous variations, polymorphism being notable. Both aerobes and anaerobes are represented, there are marked differences in resistance and fragility, behavior varies with the culture medium, and all in all the question of one or several species is more than academic. As for the source of these germs, they are omnipresent, occurring in the soil, in the clothing, in the human skin and cavities. They are seldom seen in recent wounds, and in 56 of 67 cases studied they could not be demonstrated inside of 48 hours. Yet these wounds are not to be classed as secondarily infected, for in most cases the organisms must have been present at the start. Secondary infection, while possible, is very rare. The germ is carried directly into the wound by the projectile or weapon, whether it was originally in the skin or clothing. It doubtless begins to proliferate in the marginal portion, which explains why the wound at first appears to be sterile. In about 86 per cent. of streptococcus wounds the missile was a shell fragment. The locality is apt to be one of the fleshy portions of the body—regions like the hands, scalp, etc., are very seldom involved. Hence penetrating wounds are possible, and as a matter of fact this type of wound is what is usually encountered. The per cent of this type of wound to become streptococcus-infected is very high—84 per cent. in the author's material. In the uncleansed wound streptococcus infection may be quite masked by the development of gas gangrene. If the causes of gas gangrene are not in evidence—that is, in pure streptococcus infection—we see a simple infected wound with very intense and violent inflammation. Supposing that the wound has been sutured, the first symptoms of infection are pain and fever. The latter are invariably absent in uninfected wounds. Pain is spontaneous and increased by pressure, and fever even begins on the first day while the wound still looks healthy. By the third to fifth day it has reached a sort of maximum of 38.5-39.5 C., falling by lysis until normal at the end of ten to fifteen days. This course was seen in half the cases. In a number of cases the sutures were removed, but without influence on the course of the fever. The authors believe that the infection is parietal and not cavitary. The surface appears to be progressively vaccinated by the disease products just as in erysipelas, until an immunity is reached. The edges of the wound are the seat of a peculiar edema recalling that of milk leg. The amount of redness is very moderate. The discharge is abundant and without odor and may be thin or purulent. In the great majority of cases union by first intention does not occur. If, on the other hand, the wound has been carefully cleaned out and left unsutured or has been desutured a superficial necrosis occurs in the surface of the wound, while the margins in addition to being red and swollen present small phlyctens or superficial sloughs. The discharge in this kind of wound is usually thin, seldom purulent. In from 10 to 15 days the necrotic tissue is replaced by granulations and pus now appears in the discharge. The granulation does not heal normally, and after three or four weeks the wound area is studded with proud flesh which may be more or less ulcerated—exceptionally the wound has become a vast ulcer. The infection from the laboratory standpoint may be mixed through the presence of staphylococci, coli bacilli, pyocyaneus, etc. In these mixed cases the clinical picture may or may not be altered somewhat, but generally speaking the infection is practically streptococcic. Death from sepsis is very unusual. Of the authors' material all recovered but two, and neither man died of streptococcus infection. Healing progresses as soon as the granulations become normal. The latter have a characteristic tendency to bleed readily. In making a laboratory diagnosis a number of smears must always be made because the little chains of cocci may not be seen at first. The treatment must be that of an ulcerated surface which is to heal by granulation and there is no special method. The authors apply 40 per cent. formol as a disinfectant, and when possible the area of proud flesh should be ablated and sutured. This intervention was never practised before the third week.

Nederlandsch Tijdschrift voor Geneeskunde.

June 22, 1918.

Case of Acute Pseudoleucemia.—Van Asso describes a case of the so-called Pel-Ebstein type of this affection, which is also known as chronic relapsing fever. The patient was a man aged 31, who had been in apparent good health the day before his fever developed. The family history was unusual from the coexistence in his immediate relatives of cancer, tuberculosis, and syphilis. His father had died of cancer of the stomach, mother had tabes dorsalis, a sister had syphilis of the humerus, two maternal uncles had pulmonary tuberculosis and a third died of pernicious anemia. The maternal grandfather was both tuberculous and luetic. The patient was of a phthisical habitus. His attack of fever was set down to influenza. It became apparent, however, that he was suffering from a type of remittent fever which showed no tendency to recovery. In other words, he had developed what was clinically a chronic relapsing fever. A renewed search was made for internal lesions and enlarged lymphnodes, but without success. Despite afternoon temperatures up to 104° the patient did not feel very sick. A slight tendency to hemorrhages appeared—attacks of nosebleed, petechiæ, etc., and a few enlarged lymphnodes became apparent. The blood count excluded leucemia and the spleen was not enlarged. The mucosæ were not especially anemic and the hemoglobin was 61, with 4,000,000 red cells. The case was hopeless from the start, death taking place about 4 months after the first consultation. An autopsy was not allowed.

Book Reviews.

An X-Ray Atlas of the Skull. By A. A. Russell Green, M.B., B.S. (Lond.), M.R.C.S. (Eng.). Price, $3.50. London: Longmans, Green & Company, 1918.

This atlas contains eleven plates, five of which are colored. The number of separate radiograms is twenty-seven, but this small figure conveys no idea of the resourcefulness of the representations, for the practice of coloring a portion of the radiogram is an aid in interpretation of the shadows which has not yet come into general use. The work has an introductory purpose, for it deals only with the normal skull. The only departure from this plan is a section on the general principles of locating foreign bodies. The author has employed the methods of his atlas for two and a half years in a military hospital with nearly 2,000 beds.

The Indian Operation of Couching for Cataract. Incorporating the Hunterian Lectures Delivered Before the Royal College of Surgeons of England on February 19 and 21, 1917. By Robert Henry Elliot, M.D., B.S. (Lond.), Sc.D. (Edin.), F.R.C.S. (Eng.), etc.; Late Superintendent of the Government Ophthalmological Hospital, Madras; Late Professor of Ophthalmology, Medical College, Madras, etc., etc. Price, $3.50. New York: Paul B. Hoeber, 1918.

The seven chapters of this volume are devoted to the history and technique of couching, the Hindu coucher, the couched eye and its recognition, case histories and statistics. The eight plates of illustrations comprise forty-five separate pictures. No less than 780 cases of couching are controlled under the statistics. The superheated conclusions reached are that the coucher is an unmitigated evil who should be suppressed—a dirty, ignorant, bragging, lying, swindling mountebank, who does no manner of good and no end of harm.

Etudes Sur Le Fonctionnement Rénal Dans Les Néphrites Chroniques. Par Pasteur Valery-Radot. Paris: Masson et Cie., 1918.

The author is known to be a junior collaborator of Widal and Weill. These three men acting in concert have done a vast amount of original clinical work on uremia, and the present volume covers all of the activities of Widal on the subjects of Chloride excess and uremia, including his famous prognoses of survival in association with various blood contents of nitrogen. More than this need hardly be said, for all internists and urologists who read French will read the work, which will no doubt be translated into other languages at an early date.

Surgical and War Nursing. By A. H. Barkley, M.D. (Hon.), M.C., F.A.C.S., Lecturer at Good Samaritan Training School for Nurses, Consulting Surgeon Good Samaritan Hospital, Lexington, Ky. With 79 Illustrations. Price, $1.75. St. Louis: C. V. Mosby Company, 1918.

This book is intended to embrace the practical phases of surgical and war nursing and to take an intermediate position between a reference and text book. It is written especially for the instruction of nurses and, therefore, a good deal of the material is elementary and adapted to the nurse's knowledge of surgical questions. It is clearly written and excellently illustrated and should well serve its purpose.

La Gangrène Gazeuse. Bactériologie, Reproduction Expérimentale, Sérothérapie. Par P. Weinberg, Chef de laboratoire, et P. Seguin, Boursier de l'Institute Pasteur. Prix, 20 francs. Paris: Masson et Cie., 1918.

In order to treat this subject properly it has been necessary to study intensively no less than twenty pathogenic bacilli which are known to produce lesions of the type seen in gas gangrene. These studies were all made in vitro. In the study of the disease itself a distinction is made between the classic and toxic forms, both of which are the products of the same pathogenics. Another distinction is based on isolated and mixed causes. The amount of space given to pure infections shows that these are much more common than the general public was aware, for we gain the impression that most cases are due to the symbiosis of a number of germs. Experimental gas gangrene is next considered, and the last section before we come to therapeutics is devoted to the pathology of the disease, with special reference to the conditions which favor its development. Serotherapy comprises antitoxic and antibacterial sera, univalent and polyvalent sera, and prophylactic and curative use of sera. To praise a book like this is quite beside the mark, for it is the work of the representative men of the Pasteur Institute, who have delayed four years before going upon record.

Pharmaceutical Botany. By Heber W. Youngen, Ph.G., A.M., M.S., Ph.D.; Head of the Department of Botany and Pharmacognosy in the Philadelphia College of Pharmacy; Member of the American Pharmaceutical Association, Academy of Natural Sciences of Philadelphia, Botanical Society of America, Botanical Society of Pennsylvania, etc. Second Edition, Revised and Enlarged, with 195 Illustrations. Price, $2.00. Philadelphia: P. Blakiston's Son & Company.

For many obvious reasons the use of vegetable remedies has increased largely of recent years. Owing, perhaps, to their origin, synthetic drugs are somewhat in disrepute. The coming into their own again of vegetable drugs has rendered the study of pharmaceutical botany more necessary than ever before. Pharmacognosy has come to the front as a science, and in the present edition of Dr. Youngen's work this fact is appreciated and the subject matter of botany has been revised and expanded. The book is a very useful one and the illustrations are good.

Pathologie de Guerre du Larynx et de la Trachée. Par E. J. Moure, Chef du Centre Oto-rhino-laryngologique de la 18° Region; G. Liébault, Chef du Centre Oto-rhino-laryngologique de la 11e Region et G. Canuyt, Assistant du Professeur Moure. Prix, 25 francs. Paris: Felix Alcan, 1918.

This grand octavo volume is bulky, being printed on heavy paper, but it comprises only 370 pages and the large number of text figures (128) contributes further to reduction of the text. The subject matter is divided into functional disorders of the larynx, extralaryngical injuries, wounds of the laryngotracheal conduit and their complications, the operations of tracheotomy and thyrotomy, operations for cicaturial stenoses and autoplastics. A work of this scope is almost unique and could be condensed considerably in a translation or adaptation for American needs. As far as we can learn, there is as yet no manual devoted to these war traumatisms and we suggest the feasibility of an adaptation of the present volume for that purpose.

A Textbook of Physiology for Nurses. By William Gay Christian, M.D., Professor of Anatomy, Medical College of Virginia, and Charles C. Haskell, M.A., M.D., Professor of Physiology and Pharmacology, Medical College of Virginia. Illustrated. Price, $1.75. St. Louis: C. V. Mosby Company, 1918.

This is an elementary work, intended for pupil nurses. The authors have made a judicious selection of topics to be presented and the discussion of them is, as a rule, adequate. The chapters are short and there are a number of useful illustrations. The book should prove serviceable in nurses' training schools.

Lectures on Medicine. A Handbook for Nurses. By Chalmers Watson, M.D., F. R. C. P. E., Lecturer on Clinical Medicine, Edinburgh University. Price, $1.75. New York: William Wood & Co., 1918.

This little work comprises chapters on fevers, general conditions, and affections of the different systems of the body—digestive, nervous, circulatory, renal, etc.—together with a chapter on diet. When possible each individual affection is preceded by a brief section on the pathological physiology. The speculative part of each subject is handled very briefly and conservatively and the practical part naturally outbulks the former—diagnosis, prognosis, treatment, and prophylaxis. Aside from a full chapter on diet, there is little on nursing technique, and it is not exactly easy to understand why this chapter is inserted in the work at all. The principles of diet doubtless come in pat after an account of the varied phenomena of disease, but in the present work the usual recipes and menus are well represented.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held May 3, 1918.

DR. SETH M. MILLIKEN IN THE CHAIR.

Resection of Elbow and Shoulder—Dr. ASPINWALL JUDD presented these patients, in one of whom a complete resection of the elbow and in the other a complete resection of the shoulder joint had been done. He said that he had described the operation before and was showing patients for the purpose of demonstrating the degree of function that could be obtained by this procedure. The resection of the elbow was done for a tuberculous osteomyelitis but was equally applicable to any type of osteomyelitis or any type of disease which resulted in considerable destruction of bone. The boy presented had no elbow joint at all, a complete resection having been made. The second patient had no shoulder joint. He was a farmer and was able to do his own work. He had performed a complete resection of this kind in a number of cases, among them a waiter and a barber, both of whom were able to pursue their occupations. In doing the operation the idea had been to conserve the periosteum as far as possible even if one left some small portion of diseased bone behind. Having conserved the periosteum and the muscular attachments intact he fixed these so as to get the proper pull upon the bone. The periosteum formed a sort of a tube which was packed with gauze after iodoform and ether had been poured in. This was allowed to remain until it set up considerable reaction, even until the patient had a chill. The dressing was applied in this way two or three times under anesthesia until one obtained considerable granulation tissue and subpericosteal bone.

Endothelioma of the Frontal Bone.—Drs. JUDD and A. EDWARD DAVIS presented this patient for two reasons: First, to show the result of the extensive plastic operation and, second, to ask for opinions as to whether it was advisable to attempt to replace the loss of bone tissue in this case either with bone or with a foreign substance. The boy gave a history of swelling of the right upper and lower eyelids of two months' duration. The eye was pushed downward and inward, and there was a certain amount of ectropion. The boy has also noticed a swelling at the right side of the forehead. His vision was 20/30 in the right eye and 20/20 in the left. A nodular mass was found in the lachrymal gland. At operation the lachrymal gland was excised and a piece of tumor was dissected from the orbit for examination. This was found to be an endothelioma. It was not connected with the eyeball. A second operation was performed four or five days after the first, removing the roof of the orbit and the frontal bone on the right side (the bone removed being 1½ inches in diameter), the dura mater and the pia mater, down to the brain surface, but it was not thought best to sacrifice the eye. There was a very slight diversion upward and outward and there was no motion directly inward or outward, vision being 20/30 and the fields normal. They had saved the eye, though all the frontal bone was removed on that side and the dura mater and pia mater were involved down into the brain tissue itself, but the sinuses were not involved. In considering the involvement of the lachrymal gland, it was worthy of note that, while there were many varieties of growth that affected this gland and endothelioma was very rare, Dr. L. Webster Fox reported cases of sarcoma of the orbit cured by the *x*-ray without operation. With reference to the nature of the growth, whether benign or malignant, congenital or acquired, it would seem that undoubtedly the growth was acquired in this case. It would be an advantage if the boy's eye could be saved. Plastic operations on the upper eyelid and the extended ocular muscles were not to be considered until the chance of recurrence was past. The orbital plate was entirely missing as well as a part of the frontal bone. When they began to operate they expected to take off only a piece of the orbit but they found such an extensive involvement that they took out the entire orbital plate down until they could see the optic nerve. Both the dura and pia mater were involved so that it was necessary to remove masses, one the size of an almond and the other the size of an English walnut, from the brain. The question that came up was whether the introduction of a plate would give this boy greater protection from a blow and whether at the same time a plate could be introduced without spoiling the cosmetic effect. The tumor was one of rapid growth. The boy had first consulted him on January 21, at which time he stated that he had only noticed the growth two or three months before, and yet at operation this enormous growth was found.

Two Cases Simulating Diverticulitis of the Sigmoid with Chronic Intestinal Obstruction.—Dr. JUDD presented these cases because they had both been diagnosed as diverticulitis and the diagnosis was confirmed by the *x*-ray plates. The *x*-ray plates gave the characteristic picture of diverticulitis. The one patient gave a history of ten years' standing and complained of constipation with symptoms of obstruction. Enema had no effect. The patient stated that nothing less than four ounces of castor oil had any effect, so he gave him four ounces and a large enema to produce a movement. It was assumed that they were dealing with a diverticulitis or possibly that the sigmoid was redundant and folded over on itself and that possibly at one point the lumen was completely obliterated. This was found to be the case, and when the fold was released the sigmoid ballooned and came into very good alignment. The patient made a good recovery, needed no laxatives and had gained 30 or 40 pounds.

Tuberculosis of the Breast.—Dr. JOHN A. VIETOR presented this case. He said that the patient was admitted to the hospital on November 9, complaining of pain and tenderness, and had a typical abscess of the breast, which had been forming for the past two weeks and had ruptured three days before her admission to the hospital. Examination at that time showed a typical abscess of the breast, with a sinus at the upper outward quadrant and another small sinus at about the center of the breast at the outer part. The sinus was discharging mucopurulent pus, so at operation a specimen was taken and some of the tissue was curetted off and sent to the pathologist, who reported that the discharge contained tubercle bacilli. The patient was readmitted to the hospital on December 8 and subjected to another operation, the breast being removed. There were no nodes, the *x*-ray was negative, and there was no evidence of tuberculosis anywhere else in the body. The previous history was that the patient had had six children, nine, seven, six, five, and three years, and the last, three months old. At the time the second child was born she had an abscess of the breast and it had continued to discharge ever since. The chief interest in this case lay in the rarity of the condition. Dr. Gerster stated that in the routine examination of 200 cases of breast abscesses at the Mayo clinic they had found only one primary case of tuberculosis of the breast.

Ulcerating Carcinoma of the Breast.—Dr. EDWARD W. PETERSON presented this patient, whom he stated he had not seen for two years. He had operated on her five years ago, when she was 42 years of age, at which time she gave a history of a breast growth of two years. Before coming to the hospital she had been treated by a physician who advised against surgery and had treated her with poultices, etc. The breast had a large ulcerating area and very extensive axillary involvement, and the skin was involved. Dr. Peterson said he had never seen an extensive skin involvement where there was not a recurrence. This patient was sent to Dr. Hirsch, who gave her *x*-ray treatment for about one year after the operation. When he saw the patient the last time there were no signs of recurrence; now there was a small nodule which would be treated.

Dr. SCUDDER JOHNSON WOOLLEY exhibited several *x*-ray plates made of a man, 65 years of age, who for years had suffered from abdominal pain, gas eructations, and a condition bordering on intestinal obstruction. He had noticed these symptoms fifteen years ago and had consulted physicians in Europe who made a diagnosis of intestinal stasis. He had gone along until five years ago, when he suffered from abdominal pain and fever and it was thought he had appendicitis. The appendix was explored and found normal. The kidney

was also explored at this time and no pathology found. When suffering another attack he was operated on again and the gall-bladder removed. About one year ago he became ill again. His temperature was 102° F. and he presented symptoms indicative of acute obstruction. *X*-ray plates were then taken and showed diverticuli of the rectum and the lower part of the sigmoid. It was decided not to operate on him at that time but to try medical treatment. He had gone along for practically a year on a meat-free diet, etc. Three weeks ago he had another acute attack and the *x*-ray taken at that time showed multiple diverticuli, at this time from the rectum to the cecum, and he thought that possibly there was a beginning carcinoma implanted on the diverticuli and advised operation. These plates showed multiple diverticuli all along the colon, and it would seem to be very possible in every case to make the diagnosis of this condition quite easily if one had good *x*-ray work. This man had not lost weight and did not look ill in any way whatever.

Treatment of Inoperable Cancer of the Breast by Chemical Extirpation.—Dr. CHARLES WILLIAM STROBELL presented this paper. (See MEDICAL RECORD, September 21; also August 12, 1916.)

Dr WILLY MEYER said that if he had not come to the meeting and seen Dr. Strobell's cases he would not have believed it possible to get such results by chemical extirpation, but this did not imply that chemical extirpation could be placed on the same basis as surgical excision. Dr. Strobell was deserving of great credit for having spoken of the method as only applicable to inoperable cancer, and, as he had said, the treatment of cancer by the application of caustics was known a thousand years ago. They must admit that operation as such was good for nothing before a growth that was recurrent and progressive. It stood to reason that in the presence of growth as large as several of those reported this evening there must have been some involvement of the axillary and subclavian glands. He had examined these patients carefully and found no enlarged axillary or subclavian glands. If it could be shown that inoperable cancer was amenable to this form of treatment it was worth while trying, if only to prolong life. Dr. Strobell spoke of having had one patient on Dr. Bulkley's dietetic treatment. He wished Dr. Strobell had gone more into the details of this treatment for, as we knew so little about cancer, anything that seemed to give any additional help in the treatment of this disease should be gone into. He believed that there was a possibility that diet might have some influence on the underlying condition of the individual that gave a foothold to cancer. As he had said before, the pathology of cancer was so like that of tuberculosis and syphilis—and these were infectious diseases—that he was inclined to the belief that cancer was infectious. He believed that there was some underlying condition in the system that permitted the cancerous growth to gain a foothold, and that food might influence this condition and therefore deserved attention. In the surgical excision of carcinoma of the breast, Dr. Meyer emphasized the importance of removing both the pectoralis major, the pectoralis minor, and the deep fascia. He thought that if this were done and the cases were operated on early, in from 28 to 35 per cent. there would be a prolongation of life beyond five years. He believed Dr. Strobell's method had a place in the treatment of cancer.

Dr. L. DUNCAN BULKLEY stated that he had started the Skin and Cancer Hospital because he did not believe in operation for all cases of cancer, and he hailed this method which Dr. Strobell had presented as the *summum bonum;* it took away his objections to the surgical removal of cancer. He had seen dozens and dozens of postoperative recurrences and that was the reason he was opposed to operation. Dr. Strobell had been employing this method at the Memorial Hospital, which had the approval of all the physicians who had seen with what success he removed tumors and they felt that it had a distinct value in cases in which other methods of treatment were not available. The results which were obtained were due to two factors, the active leucocytosis which was set up and the extreme care with which Dr. Strobell worked, absolutely avoiding all manipulative displacement of loose proliferating cells through vascular channels beyond the limits of the operative field. Dr. Bulkley cited several instances of severe cases of cancer of the breast that he had seen successfully treated by Dr. Strobell and emphasized the necessity of carrying out the procedure with extreme care.

Dr. J. SHERMAN WIGHT said that Dr. Strobell's paper carried him back some years ago to a time when he did somewhat similar work on inoperable cases of Dr. Coley's. Dr. Strobell had not told them how he used his preparaion. In his own work he had used an alkali, sodium hydroxide. He recalled two cases in particular which he had treated by this chemical; one was a case of carcinoma of the tongue and the other carcinoma of the breast. He injected the solution into the tumor and also into the blood current. In the case in which he made the injection directly into the tumor the tumor disappeared quite rapidly and did not recur in that locality. This case Dr. Coley had watched for a number of years. After it was pretty well cleared up there was a spontaneous recurrence in the femur and the patient died. The case of cancer of the tongue was treated by injections into the blood current and it was quite remarkable the way in which it melted down, but the man had a severe hemorrhage and died. Seeing these cases brought back this work that he had done many years ago, and it occurred to him that perhaps if he had pursued it a little further he might have found that he would obtain better results if he used the potassium rather than the sodium hydroxide.

Dr. GEORGE H. SEMKEN said that if we were asked to go back into past centuries for our treatment of cancer it might be wise to go back also in the field of philosophy and take a favorite dictum of René Descartes, namely, that one should accept all propositions with doubt. In the present matter for discussion this applied with peculiar force. Dr. Strobell's treatment consisted in the destruction of the integument with sticks of potassium hydrate, followed by the application to the denuded tissues of a mixture of zinc chloride, sanguinaria, and charcoal. Potassium hydrate, in the form of Vienna paste, had been used to destroy the skin for one hundred years. Zinc chloride had been used in the treatment of cancer since the thirteenth century. Sanguinaria had long been a favorite treatment for cancer among the North American Indians, and charcoal had been in use as a deodorant of necrotic surfaces since the time of Hippocrates. The whole combination —Vienna paste, zinc chloride, sanguinaria, and charcoal—was used by Fell many years ago, so Dr. Strobell's chemical operation was neither new nor original. It was well known that there was a great difference in the malignancy of breast cancers, and most of the cases that Dr. Strobell had described were apparently of the less malignant type that tended to remain localized for long periods and to recur late. In these a limited surgical operation or extensive local destruction might suffice for a long time, even perhaps effect a cure in a few instances. Another factor that must be borne in mind, in judging cancer treatments, was the occasional recurrence of latency—the cancerous process remaining apparently stationary even for years. In one case of this type, a recurrence involving the chest wall, the speaker removed the tumor, together with parts of the adjacent ribs and the intercostal muscles down to the pleura. The microscopic examination of the specimen showed cancer in the lowest level of the tissue removed, and it was evident that the cancer had invaded the pleura. The physical signs of an intrathoracic tumor appeared within the following six months, but the process then apparently became quiescent and remained so for about nine years, when it again became very active and extensive, and caused the patient's death within a few months. This latency could not be explained. The occurrence of the phenomenon, however, was not rare. None of the cases described by Dr. Strobell had been observed for the time necessary to a determination of his results. Dr. Strobell had stated that cancerous cervical and axillary glands, a lung metastasis, and rib metastases, supposedly present in some of his cases, disappeared after the chemical destruction of the breast tumor and of the lower axillary glands. It was a matter of knowledge to all students of cancer that when cancer obtained a foothold in any tissue it would continue to grow and develop unless destroyed by some external agency, and

the exceptions to this rule were rare. This zinc chloride chemical operation was purely local in its destructive effect, and it was inconceivable that any purely local destructive agency, applied to the primary tumor and the lowest axillary glands alone, could cause the disappearance of cancer in the remaining axillary lymph nodes, or the cervical lymphatics, or the lungs, or the ribs, as had been claimed in Dr. Strobell's paper. All enlarged lymph nodes in the axilla or the neck in cases of cancer of the breast were by no means cancerous nodes. Microscopic examination of such nodes had repeatedly demonstrated chronic inflammatory hyperplasia alone in many cases, particularly where there had been an associated erosion of the surface of the breast tumor. Dr. Strobell's last case, in which enlarged axillary and cervical lymph nodes disappeared after the destruction of the breast tumor, showed such an erosion of the primary tumor; and the subsequent behavior of these glands demonstrated rather the purely inflammatory character of the involvement. The radical surgical operation, done at an early time, was and probably would remain our main hope in the treatment of cancer. In these breast cases much could be learned from a study of the recurrences, and especial care could then be given, in the primary operation, to the regions that seemed to be the most frequent sites of recurrence. These were the skin and subcutaneous tissue about the growth, the lymphatic glands about the coraco-acromial vessels, the subscapular packet of glands, and the lymphatic glands situated immediately under the axillary skin. The radical breast operation was not a matter of forty-five or fifty minutes, but of a few hours; and since the primary operation was the patient's one chance for cure, time should never be allowed to weigh against painstaking thoroughness. With the extended radical technique excellent results had been obtained, and even in many advanced cases, that ultimately succumbed to visceral metastases, local recurrence had not occurred. The zinc chloride operation, so called, did not allow selective dissection and could not be considered a surgical procedure. If it had any place in the treatment of breast cancers, it was in those advanced cases where the removal of the tumor by operation was impracticable or would be attended by considerable loss of blood, and also in those cases in which the patient's low vitality would contraindicate any severe operation. If the cancerous process involved the soft parts alone, the zinc chloride destruction might remove the growth, but it could not be effective if the tumor had eroded the underlying ribs, as was so often the case with recurrences. It seemed evident, therefore, that the potassium hydrate-zinc chloride procedure should be limited to a very few cases; and even in these it was not clear that the method possessed any advantages over the actual cautery. With reference to Dr. Bulkley's case of the disappearance of a breast tumor without other treatment than a vegetable and cereal diet, the objection must be raised that the diagnosis of cancer in this case was made by palpation and not by microscopic examination. The disappearance of the tumor, therefore, was not an evidence of an effective cure, but it was a proof that a wrong diagnosis had been made.

Dr. Willy Meyer said that he did not understand how these glands, if they were present in the axilla and along the side of the subclavian vein, were absorbed. All he could say was that there were no enlarged glands present in these patients and that it was beyond his comprehension. He did not mean by this that they should go back to the chemical treatment of cancer. Surgical treatment was the proper thing and it must be early and thorough.

Dr. Strobell, in closing the discussion, said the work he presented was based on cold scientific facts, which he had followed up very carefully and knew to be true. He had been working on the proposition for eighteen years. The first case he had treated with caustics lived for eight years after the treatment was applied, without ever a sign of recurrence, finally dropping dead in the street of heart disease. This woman had a typical advanced carcinoma of the breast, and when the speaker was called to see her, he told her that nothing would do any good but the knife, and urged immediate excision. This she refused, saying that she would rather die, and that she wished him to use caustics. Being an old patient, the speaker did not feel like leaving her to suffer without trying to do something for her, so, after consideration, and although very sceptical, he decided to employ an arsenical formula (Marsden's). The cancerous area was covered with the preparation and also spread out a little beyond over the adjacent skin. This was not disturbed for four days, when cataplasms of flaxseed were applied to hasten the separation of the devitalized tissues. This process over, the resulting clean wound soon healed. After a period of four months, the patient came back with a recurrence, which was wholly expected by the speaker, and again she was told that nothing but the surgical operation would do, that she must submit to without delay. She again refused and asked that the former treatment be repeated. This was done, but very much more extensively than the first time. The patient made a recovery, lived for a period of eight and a half years, without sign of recurrence, and died suddenly as stated. After this experience the speaker was convinced that there was something in that form of treatment; that if such a thing could happen in one case, it could in others. He therefore began to plan, and to work out a practical procedure, which had culminated in the present perfected painless technique. As time went by the conclusion was reached that, if all sensitive structures were removed by potassium hydrate as a first step under hyoscine-morphine narcosis, he could then apply the zinc chloride, with which he was working, painlessly, provided always, however, that the devitalizing mixture be kept from running over on to the adjacent intact skin. Just here was where the rôle of the charcoal ingredient of the zinc compound came in, as it was not at all intended to serve any other purpose than that of identification, for by its blackening effect upon the mixture, the least little speck, could be detected which, if left unnoticed, would entail suffering. The proposition of Dr. Semken, that the speaker had discovered nothing new in the agents used, namely, zinc chloride and sanguinaria, and charcoal, and potassium hydrate, was of course true, they were simply the tools with which the speaker was able to do his operation. It was the scope of the operation, the manner of application of the chemical agents in an effective yet painless way, and the fact of the enucleation of enlarged metastatic lymph nodes with chemicals that was absolutely modern, and not to be found in previous literature. The value of zinc chloride as a safe escharotic was first established by Canquoin of Paris in 1838, after a long series of experiments with all the known caustics to determine their relative values. It was the active agent employed at the Middlesex Hospital, London, in cancer work in general, the arsenical preparations having been considered too dangerous. It was the caustic employed there by Fell and Patterson. The method had been worked out on a scientific basis under the eyes of men who were recognized authorities on the treatment of cancer, and it had throughout been the desire of the speaker that the work should reach the laity through the legitimate channels, believing this to be the only right and safe course to pursue, to preserve it for the benefit of humanity for all time.

Dr. Willy Meyer asked Dr. Strobell how he explained the disappearance of the axillary and other glands, in a certain proportion of cases.

Dr. Strobell said he could not offer an entirely satisfactory scientific explanation. Eight years ago, when he published the first results of this operation, he had investigated the records of a large number of cases, making an examination of the pathological reports, and it seemed that about 60 per cent of the cases were free from axillary involvement or at least the pathological reports did not mention it. This he had done because he had observed that frequently enlarged glands disappeared after the cancerous breast was removed, and he was inclined to think that frequently enlarged axillary glands were not metastatic in the disease, but simply inflammatory. How much the direct action of a chemical (chemical drive) was responsible he could not say. When in his cases the enlarged axillary lymphatics were also to be removed, the primary denudation was extended to include the axilla which cleared the way for the destruction of the glands; this was accomplished wholly with potassium hydrate, the agent used in the denudation. Dr. Strobell said that he desired to ex-

tend the knowledge of the operation, but that it should only be done by surgeons who had mastered the technique. It was a surgeons' job and it was for them to do. The question had been asked by Dr. Levin regarding the effects of chloride on bone, he would answer that it would cut its way through any living tissue, even bone, and that the devitalized portion of bone would be separated from the living by the line of demarcation, would slough off, and the bone would renew itself perfectly. Concluding, the speaker referred those interested to Dr. W. S. Stone's most interesting article "Review of the History of Chemical Therapy" which appeared in the October 7, 1916, issue of the MEDICAL RECORD. Strange as it might seem the facts therein stated were new to the speaker who had then carried out an independent line of investigation unhampered by tradition, except such as one heard every day at the cross roads and read in the Pharmacopœias.

Congenital Hydronephrosis.—Dr. CHARLES E. FARR reported this case and exhibited the specimen. He stated that the patient was a colored boy, six weeks of age, who had a large cystic swelling in the left side of the abdomen. The diagnosis made was probably hydronephrosis. A laparotomy was done under local anesthesia, one-half per cent. cocaine. The large cystic kidney herewith presented was found. They were unable to find the right kidney. At the end of twenty-four hours there was no secretion of urine. The important point in this case was that the operation was performed on the child at the age of six weeks.

A New Blood Transfusion Apparatus.—Dr. J. SHERMAN WIGHT presented and described a small apparatus for blood transfusion which did away with the use of the syringe and cannula. He also presented a blunt dissector which was to be used in place of the Mayo scissors. In using the Mayo scissors the movement on the part of the operator was one of extension which was very tiresome, while with the instrument presented the movement was one of flexion.

AMERICAN ORTHOPEDIC ASSOCIATION.

Thirty-second Annual Meeting, Held in Washington, D. C., April 22 and 23, 1918.

DR. JOHN L. PORTER OF CHICAGO, PRESIDENT.

(*Concluded from page* 792.)

Foot Disabilities in the Military Service.—Major HAROLD D. CORBUSIER, M.R.C., read this paper which was a preliminary report on the reconstruction of recruits. The march constituted one of the chief duties of a man on campaign. A successful march placed the man at their destination in the best condition. Unless the soldier could reach his place in the firing line, he was useless as a rifleman. It was often seen in military maneuvers that many stragglers limped into camp late at night, as they were not able to keep up with the march. Napoleon had said that the general who produced the best military shoe would do most to produce an efficient army. This was most true at the present crisis. The American foot seemed particularly prone to disability. The man needed to be trained to make the best possible use of the legs and feet. Battles were won and lost by legs as well as by rifles. Military service put the most unusual strain on feet accustomed only to the demands of civil life. Flat foot was a common cause of disability. Of 12,000 soldiers, 960 had flat feet to some degree. Among the drafted men it was supposed that there would be exaggerated symptoms, but it was found that there were 9.25 per cent flat feet among the volunteers and 7.25 per cent among the drafted men. However there were always to be found genuine malingerers. The psychology of the men was a matter for careful observation. It was unwise to inform the malingerer that he was suspected. The best treatment was by hard and unpopular duty. These men often asked to be sent back to regular line duty, the treatment having proved too vigorous for comfort.

Major E. R. RICH, M.R.C., said ideas had changed durinng the past six months, many having gone by the board. In the South the special point they had been laying emphasis upon was the weight bearing capacity of the foot. With this in mind feet were classified into four groups: (1) acute foot strain; (2) weak feet, requiring ordinary felt pad for support; (3) ankle valgus; in this the weightbearing function was thrown where it belonged; (4) lateral arch conditions. Here the weight was thrown outside of the foot. Correction and support were needed.

Lt. Colonel C. L. STARR said that he had learned by experience some things in regard to foot strain. One point was in regard to operation. No man operated upon would be fit for line duty. A certain degree of flat foot could be used in front line work, but when it passed that point it was no good to try and use it. The man was a nuisance to the officer and to his fellow soldiers. It was best to put these men into the line of communication. A man with claw feet could never make a soldier. It was impossible for him to march and carry a pack for 20 miles. He could be put into the labor battalion for the line of communication work. Many men come into the camp with muscularly weak feet, and the drill was made too hard at the beginning and carried too far, with the result that the feet gave way. A little more judgment in the early stages of the training would eliminate much foot strain. It was noticeable when many men were drilling that the drill sergeant made them place the feet at an angle of 45 degrees. He thought the Association should make its opinion known that this was very bad. The position of attention should be with the feet parallel instead of at 45 degrees.

Dr. MYERS, of New York said that there was a point to be observed in regard to the short tendon of Achilles. It would be well to consider whether a flat foot could be improved by exercise or would continue flat. A very short tendon indicated hypertrophy of the calf muscles and exercise would increase the difficulty. With the anterior muscle exercise would be more beneficial.

Major J. RIDLON, M.R.C., said the question was what flat feet should be rejected by the examination boards. The answer was that all rigid feet should be rejected. All flexible feet, so far as arches went, should be accepted. As to the short Achilles tendon, if not actively painful, it could be compensated in one of two ways: a stiff shank could be worn so that there was no motion between the os calcis and ball of the foot, or the heel of the shoe could be raised. The question as to what operations should be done on recruits to make them fit for service, should be answered by saying that no operations should be performed.

Major C. RYERSON, M.R.C., said that not enough had been said about traumatism of the foot due to arthritis. There were some cases in which the patient should be operated on. Simply to remove the part of the metatarsal head that was causing the trouble, by chiseling off the inner side, would result in producing a normal foot within three weeks.

Dr. H. P. H. GALLOWAY, of Ottawa, said he had listened with a certain degree of amazement to the account of efforts made for the salvage of physically imperfect men. He was glad to hear Colonel Starr speak of the Canadian view point in this matter. Canada had sent 100,000 soldiers and had made nothing like the attempts at reclamation which had developed already in the United States Army to fit the men for service abroad. Men operated on to make them fit for service in the front line would in time be found liabilities rather than assets. Positions should be found for these men in the army where there would be comparatively little demand upon their marching capacity.

Captain H. LEWIN, M.R.C., said that at Camp Grant he had found among the men a chiropodist and a masseur, and he had found them very helpful. The chiropodist taught him many useful hints in regard to putting pads on the foot. At Camp Taylor there was neither chiropodist or masseur and he would have been glad of their services. In regard to the making of flat feet by too strenuous drill there was another point to be noticed. Men in hospital with grippe and tonsillitis were allowed to walk around all day in slippers. This was at a time when all the body tissues were relaxed from recent infection and there was no support for the foot. This was extremely undesirable. He had always insisted that the regular shoes be sent over and the necessary support thus given.

Captain MARSHALL, M.R.C., said that the malingerer was a bad class of individual to deal with. Very often the medical officer was positive that there was nothing wrong and yet it was very difficult to prove. These persons were often of very low order of intelligence. One point he thought should be brought to attention of the line officers. At Camp Taylor he had noticed that the new recruits were put on 40 hours drill before they were fitted with army shoes, or when they had just been given new shoes. This was a very probable cause of disability.

Major S. C. BALDWIN, M.R.C., agreed with Colonel Starr that one could not make good soldiers out of men with bad feet, but it was necessary to give them what treatment one could. He could not agree with Major Corbusier, who objected to supporting the long arch of the foot and yet supporting the transverse arch. If the longitudinal arch should not be supported, why should the transverse; both would weaken the muscles. The thing to do was to give more treatment and use such supports as would keep the arches up until strong enough to be given more weight and tension. This could be done by giving more exercises and baths and keeping the feet in a correct position. The support should not be under the heads of the metatarsal arch, but back of the heads of the metatarsals. This would give support without irritation of the joints.

Dr. I. NATHAN said that he had never seen men with relaxed feet, that is those in whom the ligaments and muscles had been stretched, who were able again to use their feet as the normal person does.

Dr. C. RILEY said that in the examining boards they had been putting flat feet into class C. The direction of the os calcis should be considered. It should be slightly upward, forward, and outward, and if it were turned another way there would be trouble.

Dr. JOHN PORTER, of Chicago, said he had seen men with flat feet who were discharged although they had perfectly strong feet. He recalled the story of a mountaineer who had gone to the camp to enlist and was turned down because he had flat feet. He complained bitterly at this decision and said that he had walked 120 miles to enlist and did not want to have to walk back again.

Major H. CORBUSIER said that according to regulations one should not accept cases of subluxation of the foot. But one should find out if the man has symptoms or not. The suspected case should go into training camp.

Major J. T. RUGH said that the transverse arch condition was extremely rare. In regard to the special reconstruction sections, it was necessary for the orthopedic men to instruct the officers how to drill the men. The men would suffer if the regular officers did not understand these questions.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE STATE MEDICAL BOARD OF THE ARKANSAS MEDICAL SOCIETY.

Little Rock, May 14 and 15, 1918.

(*Continued from page 750.*)

BACTERIOLOGY.

1. (*a*) Give formula of Gram's strain. (*b*) Anilin water.

2. (*a*) What is the duty of the lymphatic system when the body is invaded by bacteria. (*b*) How is such duty performed. (*c*) Name five diseases that are manifested by lymphatic nodes.

3. Mention some of the bacteria of the normal body and give sites especially found.

4. Discuss autoinfection.

5. Differentiate infectious and contagious diseases. Give example of each.

6. Define active and passive immunity.

7. (*a*) Mention two or more diseases produced by spirochetic organisms. (*b*) Two produced by *Diplococcus intracellularis*.

8. What is the special value of Gram's method of staining.

9. Discuss the communicability of syphilis, giving the sources and essential factors in the infective process.

10. Discuss the distribution and pathogenicity of colon bacilli.

PATHOLOGY.

1. Discuss the etiology and pathology (*a*) of Hodgkin's disease, (*b*) of rheumatism.

2. (*a*) Define phlebitis. (*b*) Discuss etiology and mode of termination.

3. Discuss the mechanism of a rise in body temperature and name the more common tissue alterations that accompany the same.

4. (*a*) What is normal systolic and diastolic blood pressure. (*b*) Give cause of variations found in health.

5. Discuss the etiology of cervical and submaxillary adenitis.

6. Differentiate histologically sarcoma and carcinoma.

7. Discuss the etiology and pathology of trachoma.

8. (*a*) Discuss the criteria of malignancy. (*b*) Name three tumors giving sites which are usually malignant. (*c*) Name three tumors giving sites which are not malignant.

9. Discuss the etiology and pathology of chronic osteomyelitis.

10. Discuss the differential diagnostic value of hematuria as a symptom.

THEORY AND PRACTICE OF MEDICINE.

1. What diseases produce conditions of the skin which are of general diagnostic value?

2. What does the urine reveal as to color, specific gravity, quantity voided, abnormal constituent, etc., in a typical case of diabetes mellitus?

3. Define simple acute stomatitis; at what age is it most common, and what is its treatment?

4. Give the physical and rational signs of pericarditis before and after effusion.

5. Define epidemic parotitis. What complications may arise in the course of this disease?

6. What are some of the serious complications which may result from an abscess in the middle ear?

7. Differentiate between sunstroke and apoplexy. Give treatment for sunstroke.

8. Give the diagnosis and treatment of acute follicular tonsillitis.

9. Give the etiology, symptoms, and treatment of cirrhosis of the liver.

10. Give the etiology and outline the treatment for acute gastritis.

OBSTETRICS.

1. Describe the true and the false pelvis.

2. Describe the fully developed umbilical cord.

3. (*a*) Give causes of adherent placenta. (*b*) Method of delivery.

4. How would you treat a case of puerperal sepsis?

5. Differentiate vertex from breech presentations and L. O. A. from R. O. A.

6. What are the indications for the induction of premature labor?

7. State how you would perform the induction of premature labor.

8. Name accidents which may occur during the first, second, and third stages of labor, (*a*) to the mother. (*b*) to the child.

9. Is the performance of craniotomy justifiable? If so, when and how would you perform craniotomy?

10. Give indications for use of pituitrin. How would you use same?

ANSWERS.

BACTERIOLOGY.

1. *Gram's stain* is made as follows: Five c.c. of anilin oil are shaken up thoroughly in 125 c.c. of distilled water. This is then filtered, and is known as *anilin water*. To 108 c.c. of this anilin water are then added 12 c.c. of a standard alcholic solution of gentian violet.

Gram's iodine solution contains 1 gm. of iodine, and 2 gm. of potassium iodide, in 300 c.c. of distilled water.

2. When the body is invaded by bacteria, the duty of the lymphatic system is to protect the body. This is

done by the germicidal action of the lymph nodes, and the lymph nodes also filter out the microorganisms from the tissue fluids. The lymphatic nodes are involved in:—Tuberculosis, carcinoma, leukemia, Hodgkin's disease, and typhoid fever.

3. The colon bacillus is always present in the intestines; Doederlein's bacillus is found in the vagina; bacillus xerosis, on the conjunctiva; pneumococcus, various staphylococci, streptococci and spirilla in the mouth; staphylococci, streptococci, colon bacillus and tubercle bacillus, on the skin, and under the nails; the smegma bacillus under the prepuce; a micrococcus in the cerumen of the ear.

4. *Microbal autoinfection.*—"When the intestinal canal is injured, or its action hindered by strangulation, etc., *B. coli* or other bacteria ordinarily harmless may pass through the injured walls and cause peritonitis or general infection. Under certain conditions, as during the debility due to hot weather, the bacteria in the intestines cause, through their products, irritation, and in children even serious intestinal inflammation. Long after an acute gonorrhea has passed gonococci may remain in sufficient numbers to cause a new inflammation or produce infection in others. A cystitis may run on chronically for years, and then suddenly become acute or spread infection to the kidneys. A persistent gonorrheal vaginal infection may lead to a gonorrheal endometritis, or peritonitis or salpingitis, under suitable conditions. The staphylococci in the skin and the colon bacilli and pyogenic cocci in the fecal discharges may also be carried into the bladder and uterus and produce septic infection. Persons carrying diphtheria bacilli in their throats or typhoid bacilli in their gall-bladder may, under predisposing conditions, develop diphtheria or typhoid fever. Blind abscesses at the roots of the teeth or elsewhere may be the cause of a slow dissemination of pyogenic organisms to the joints, the heart and other parts of the body."—(Park's *Pathogenic Microorganisms.*)

5. An *infectious disease* is one which is caused by the entrance of pathogenic microorganisms into the body, and their proliferation there. *Example,* septicemia.

A *contagious disease* is one which is readily communicable, as smallpox. The term has long been abolished from scientific medicine.

6. *Active immunity* is that form of acquired resistance to infection which is brought about by the activity of the cells of a person or animal as a result of having had the disease, or as a result of artificial inoculation with a modified or attenuated form of the causative microorganism.

Passive immunity is that form of acquired immunity which depends upon defensive factors not originating in the person or animal protected, but is passively acquired by the injection of serum from one that has acquired an active immunity to the disease in question. It is a sort of secondary immunity acquired by virtue of having received antibodies actively formed by another animal that has had to resist the infecting agent in order to produce them.—(From Kolmer's *Infection, Immunity, etc.*).

7. *Diseases produced by spirochetes:* Syphilis, yaws, Vincent's angina, and relapsing fever.

Two diseases produced by Diplococcus intracellularis: Cerebrospinal meningitis, gonorrhea.

8. The *value of Gram's method of staining* lies in the fact that some bacteria retain the stain, while others give it up. This is made use of to differentiate certain microorganisms which resemble each other in size and shape.

9. *Communicability of syphilis.*—"The infective agent of syphilis is readily and most frequently conveyed by direct inoculation with the exudate from some lesion of a victim of the disease. This most frequently occurs during sexual intercourse, but may take place in many other ways, either through direct or indirect transmission to abraded or wounded surfaces of the infective exudate. Syphilis may also be congenitally transmitted, apparently, either from the father or the mother. But the transmission of the infective agent through the placental blood is the more common."—(Delafield and Prudden's *Pathology*).

10. The Colon Bacillus. *Distribution.*—In man the *Bacillus coli* appears in the intestine normally soon after birth, at about the time of taking the first nourishment. From this time on, throughout life, the bacillus is a constant intestinal inhabitant apparently without dependence upon the diet. Its distribution within the intestine is not uniform, it being found in the greatest numbers at or about the ileocecal valve, diminishing from this point upward to the duodenum and downward as far as the rectum. It has been found in the portal circulation and, at autopsy, in the tissues and blood without there being visible lesions of the intestinal mucous membrane.

Pathogenicity: In man a large variety of lesions produced by bacillus coli have been described. It is a surprising fact that disease should be caused at all by a microorganism which is so constantly present in large numbers in the intestine and against which, therefore, it is to be expected that a certain amount of immunity should be developed. It is probable that none of the poisonous products of the colon bacillus is absorbed unchanged by the healthy unbroken mucosa and that, therefore, the microorganisms are, strictly speaking, at all times, outside of the body proper. Under these circumstances, no process of immunization would be anticipated. It is also possible that when an infection with bacillus coli does occur, the infecting organism is one which has been recently acquired from another host, having no specific adaptation to the infected body. Virulence may possibly be enhanced by inflammatory processes caused by other organisms. Colon infection may also occur because of unusual temporary reduction of the resistance of the host. Altered cultural conditions in the intestine may possibly cause increased virulence of the bacillus. Conditions due to infection with the bacillus are: Septicemia, Winckel's disease, cholera nostras and cholera infantum, peritonitis, inflammatory conditions of liver and gall bladder, pancreatitis, cystitis, pyonephrosis, and localized suppurations particularly about the anus and genitals. —(From Hiss and Zinsser's *Bacteriology*).

PATHOLOGY.

1. *Hodgkin's disease.*—The etiology is unknown. There is a hyperplasia of the lymph glands interfering more or less with their functions. The enlargement may be confined to one isolated gland, or a number may be affected in different portions of the body, or a number in one location may be simultaneously affected, causing a tumor varying in size from an egg to an orange or even larger. The spleen and liver are involved in two-thirds of the cases. "The marrow of the long bones may be converted into a rich lymphoid tissue" (Osler). The red blood corpuscles are decreased in number and altered in size and shape; the white blood corpuscles may be slightly increased in number, but there is no approximation to anything like leucocythemia.—(Hughes' *Practice of Medicine*).

Rheumatism.—"While the excitant of acute rheumatism is unknown, there is much reason to believe that some phases of it at least should be classed among the infectious diseases. There are no characteristic lesions; but various joints are frequently the seat of slight exudative inflammation, serous or fibrinous in character. Albuminous degeneration of the visceral cells with hyperplasia of the spleen has been noted. The disease is not infrequently complicated by endocarditis or pericarditis, by exudative inflammation of the lungs or pleura. Various microorganisms have been found in the body in acute rheumatism; of these the pyogenic cocci have been most frequently isolated, but these are probably to be regarded only as excitants of the suppurative or other complications. It is possible that more than one form of infection is embraced under the designation of rheumatism."—(Delafield and Prudden's *Pathology*).

2. *Phlebitis* is inflammation of the wall of a vein. It may be *caused* by injury, pressure, thrombosis, gout, septic wounds, inflammatory lesions outside the vein. It often accompanies varicose veins. It may *terminate* in absorption of the thrombus and return of the vein to its normal condition, or the vein may become obliterated; embolism may follow the dislodgement of the thrombus; pyemia may result from disintegration of a septic thrombus; edema may also result.

3. The *rise of temperature* in fever depends primarily upon an increase in the metabolic combustion. Oxygen

is used in larger amount than is usual, while the combustion products, carbonic acid, and the nitrogenous substances, urea, uric acid, etc., are excreted in greater abundance. This increased combustion is usually associated with disturbances of digestion and assimilation of food, so that the abnormal heat production is effected largely at the expense of the body proteids of the various tissues and organs concerned in metabolism. But with the increased heat production there usually occur, in the earlier periods of fever, such disturbances in the vasomotor control of the cutaneous bloodvessels as lead to their contraction. Thus, heat elimination is retarded. In later periods the vessels of the skin may dilate so that, in spite of its persistent dryness and lack of the cooling effect of sweat evaporation, there is an excessive loss of heat from this source. This is not sufficient, however, to balance the excessive heat production. In the great majority of cases fever is due to the presence in the body of deleterious substances, either introduced from without, or, more commonly, produced within the body. These are most often formed in infections, and arise either from the growth in the tissues of pathogenic microorganisms or from the distintegration of their bodies; that is they are *toxins* or *endotoxins*. But there is abundant evidence that fever is not infrequently due to perverted metabolism of the tissue cells, leading to the formation of toxic substances. Such self-engendered substances are called *autotoxins*. Certain drugs, various bacterial toxins, and organic substances introduced from without may induce fever. Exactly how these various substances act in the incitement of fever is unknown. But one assumes that the cell metabolism is disturbed by the poison, while the heat regulating mechanism is so modified that the normal balance is overthrown. That the nervous system may play an important role in these disturbances is indicated by the fact that more or less persistent elevations of temperature may follow puncture or hemorrhage in the corpus striatum or lesions of the bulb or certain other affections of the nervous system.—(From Delafield and Prudden's *Pathology*).

4. The *normal systolic pressure* in man is about 120 mm. of mercury; the *normal diastolic pressure* is about 100 mm. of mercury.

Arterial blood pressure may be *increased* by the force and rate of the heart, by constriction of the peripheral arterioles, by increase in the volume of the blood. It may be *decreased* by dilatation of the arterioles, decrease in the force and rate of the heart, and decrease in the volume of the blood.

5. *Cervical and submaxillary adenitis*, may be caused by peripheral irritation such as eczema, pediculosis, otorrhea, and affections of the lips, throat, or salivary glands. Tuberculosis and syphilis are also causative conditions.

6.

SARCOMA.	CARCINOMA.
Origin; entirely mesoblastic (Connective - tissue type).	Epiblastic and hypoblastic (Epithelial-tissue type).
Stroma; intercellular. Rarely forms alveoli.	Vascular connective tissue, which surrounds and forms the walls of the alveoli; these communicate with one another, and contain masses of epithelial cells.
Cells; granulation tissue or embryonic connective-tissue cells; shape and size vary.	Epithelial cells contained within alveoli; shape and size vary.
Intercellular substance; may be present.	Absent, or merely fluid.
Vessels; embryonic in character. They are in direct contact with, or may be formed by, the special cells, slightly modified, of which the tumor is composed.	Well developed; entirely contained within the connective tissue stroma, and supported by the walls of the aveoli. Seldom in contact with the cells.

—(Coplin's *Pathology.*)

7. TRACHOMA.—*Etiology:* "Trachoma is caused by contagion from another eye, being transferred through the secretion. The danger of contagion depends upon the amount of secretion in any given case. The transfer from one eye to another may take place by the finger, but usually by towels, handkerchiefs, and the like, which are used in common by many persons. Hence the disease spreads most extensively in schools, asylums, and barracks, and among people who live crowded closely together, and who are careless in regard to cleanliness. It is found most frequently among the poorer classes. The contagious principle in the secretion is thought to be a microorganism; a number of such have been described, but so far no conclusive results have been arrived at."—(May's *Diseases of the Eye*).

Pathology: The conjunctiva is inflamed and follicles are formed; these latter, instead of being absorbed as in follicular conjunctivitis, produce permanent granular masses, spreading over the surface of the entire lid, and presenting, in extreme cases, the characteristic appearance of a bunch of grapes of a deep-red color. The upper lid is generally first affected. Where the follicles are abundant, the conjunctiva is destroyed. Ulceration takes place, and the necrosed membrane is replaced by scar-tissue. The disease is chronic, and progresses many years, new nodules forming while others are ulcerating and cicatrizing. The bulbar conjunctiva is not usually involved.

8. *Malignant tumors* are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

Three malignant tumors: (1) *Carcinoma* (breast, stomach, rectum, uterus). (2) *Sarcoma* (bone, lymphatic glands, breast, ovary). (3) *Epithelioma* (lip, tongue, bladder, stomach).

Three non-malignant tumors: (1) *Fibroma* (uterus, ovary, testicle). (2) *Adenoma* (breast, prostate, thyroid, ovary. (3) *Chondroma* (bones, salivary glands, testicle).

9. *Chronic osteomyelitis* "generally is a condition following the acute form as a result of a retained sequestrum. The changes in this disease are more marked in the bone than in the marrow. There are two varieties of the chronic form: *osteoporosis*, in which absorption takes place with an increase in the size of the Haversian spaces. The bone becomes more spongy, and the enlarged spaces become filled with marrow; *osteosclerosis*, in which there is an increased formation of bone, particularly beneath the periosteum, but also within the marrow cavity. The subperiosteal deposit may be very dense and possess an ivory-like eburnation."—(McConnell's *Pathology*).

10. *Hematuria* may be due to (1) conditions in which the blood is affected, as in the infectious diseases, in scurvy, pernicious anemia, and purpura; (2) to traumatisms or inflammations in any part of the urinary tract; (3) to congestion of the kidneys secondary to disease of the lungs, heart, or liver. In *renal* hematuria the blood and urine are intimately mixed, tube casts are apt to be present, and there may be renal colic or pain in the lumbar region. In *vesical* hematuria the blood and urine are not so well mixed, and pure blood is apt to be passed at the end of urination.

THEORY AND PRACTICE OF MEDICINE.

1. Certain infectious diseases (typhoid, typhus, variola, measles, scarlet fever, varicella, erysipelas, syphilis, leprosy), acute yellow atrophy of liver, biliary cirrhosis, Addison's disease, chlorosis, progressive pernicious anemia, purpura.

2. In *diabetes mellitus*, the urine is pale in color, the specific gravity is usually high (1030 to 1045), the quantity is greatly increased (5 to 30 pints or more), and it contains glucose; acetone, diacetic acid, beta-oxybutyric acid and albumin may also be present.

3. *Simple acute stomatitis* is an acute catarrhal inflammation of the whole or a portion of the mucous membrane of the mouth and tongue, characterized by pain, redness, swelling, restlessness, slight fever, fetor of the breath, and disordered secretion. It is most common in infants and children. It results from the introduction of irritants into the mouth, gastrointestinal disturbances, delayed dentition, and the infectious fevers. *Treatment* consist in removing the exciting

cause, cleanliness of the mouth, attention to the diet, washing out the mouth at frequent intervals with cold water, Dobell's solution diluted, or solution of nitrate of silver (two grains to the ounce).

4. *Pericarditis.*—The symptoms are somewhat obscure and may be masked by previously existing disease. Taking a typical case as it occurs in the course of rheumatic fever, we usually find precordial distress; sharp pain is rare, but when present it is most marked at the lower end of the sternum. Moderate fever, or exacerbation of already existing fever, at the onset; dyspnea, and dusky appearance of the face; rapid action of the heart, sometimes with feeble pulse; symptoms due to pressure by the fluid on the neighboring organs (trachea and esophagus, etc.); great restlessness. These symptoms, it must be understood, are due to the presence of fluid effusion. If the pericarditis remains dry, there may be no symptoms, or at most slight precordial pain.

It is evident that we must rely more upon physical signs than subjective symptoms for diagnostic information.

Physical Signs.—1. *Before effusion of fluid.*—On auscultation is heard the characteristic "to-and-fro" friction rub, variable in intensity, and not accurately synchronous with the cardiac sounds. It usually begins at the base of the heart and then extends more or less over the whole surface. The friction may sometimes be felt by the hand (friction fremitus). It becomes less pronounced as the effusion increases, but is rarely entirely absent at the base until complete resolution or organization takes place.

2. *Effusion stage.*—The physical signs are marked increase of the cardiac dulness; displacement of the apex beat; muffling of the heart sounds; displacement of other organs (if effusion is great). The shape of the dulness is characteristic. It is conical, the apex of the cone being truncated, and situated at the level of the second rib, owing to the close attachment of the pericardium to the great vessels at this point. The apex beat is generally pushed upwards and to the left. It lies, when it is palpable at all, distinctly within the left border of cardiac dulness, not, as in enlargement due to valvular disease, in close relationship to it. The marked distention of the pericardial sac surrounds the heart limits of the organ itself. The amount of bulging and displacement of organs will, of course, vary with the amount of fluid present. As resolution takes place the friction returns, and may be very coarse in character. Muffling of the heart sounds is not always present, and is not entirely due to the presence of fluid. The muffling is therefore due mainly to weakness of the cardiac muscle from accompanying myocarditis, although where the quantity of fluid is very great, in serious and chronic pericarditis, this may in part account for it.—(Wheeler and Jack's *Handbook of Medicine*).

5. *Epidemic parotitis* is inflammation of the parotid gland (or mumps), occurring in a large number of people at the same time.

Complications: Orchitis, vulvovaginitis, mastitis.

6. *Complications of abscess of middle ear.*—Abscess of cerebrum, cerebellum, or mastoid process; necrosis of the auditory ossicles or of temporal bone; meningitis; thrombosis of lateral sinus.

7. In *apoplexy* the temperature is usually normal, the pulse slow, the breathing stertorous, and there is local paralysis (hemiplegia or monoplegia). In *sunstroke* the temperature is raised, the pulse rapid, the breathing is not stertorous, and there is no paralysis.

Treatment of sunstroke.—The patient should be immersed in a bath gradually cooled by ice, an ice pack should be placed on head and neck, the body and limbs should be rubbed. The patient should be taken from the bath when his rectal temperature falls to 102°F. Cardiac stimulants may be necessary.

8. *Acute follicular tonsilitis.*—The onset is accompanied by chills, rigor, fever, severe pains in back, limbs and throat, dysphagia, and tenderness at the angle of the jaw. The tonsils are swollen and are studded with yellowish-white points; pain in the ear is common. Coated tongue, anorexia, depression, rapid respiration and pulse are also noted. The condition is to be diagnosed from diphtheria. In this latter condition the fever is not nearly so high, there is a white membrane, which spreads to the pharynx, uvula, and soft palate, which leaves bleeding points when it is removed, and which contains the bacillus of diphtheria; this membrane recurs after removal.

Treatment.—The patient should be in bed; calomel (followed by a saline) should be given to open his bowels; sodium salicylate, gr. x-xv, q.3 h. may be given; hot fomentations externally are of service; potassium chlorate may be used as a gargle or sucked, in the form of tablets. Antiseptic sprays have been used; if an abscess forms it should be opened. Tonics, and nourishing food are indicated during convalescence.

9. CIRRHOSIS OF THE LIVER. *Etiology:* "The prolonged use of alcoholic stimulants, gin, whiskey, beer, or porter is perhaps the most common cause. It may also be due to malaria, syphilis, passive congestion, and irritation of the gall-ducts. The cause may be undiscoverable. It usually occurs in men past thirty-five years of age. The uric acid diathesis may be a causal factor.

Symptoms: "All the manifestations of hepatic cirrhosis are due to the obstruction to the portal circulation which it induces. Persistent gastrointestinal catarrh attended by anorexia, fetor of the breath, nausea, epigastric distention and distress, flatulence, and constipation are present. When accompanied by attacks of jaundice in a drinking man, the early stage of cirrhosis of the liver should be suspected. As the condition progresses and the obstruction becomes more marked, hemorrhages from the nose, esophagus, stomach, or intestine, hemorrhoids, dilatation of the superficial abdominal veins forming the '*caput medusæ*,' ascites, enlargement of the spleen, and swelling and edema of the feet occur. The condition is afebrile, and emaciation, localized abdominal pain, and sometimes jaundice are present. In *atrophic cirrhosis* the liver dullness is enlarged at first, but later becomes markedly lessened. Splenic dullness is enlarged. The skin has a muddy appearance and there is gradual emaciation. The symptoms continue from two to four years, terminating fatally in about one year after the dropsy makes its appearance. The urine is scanty, high-colored, of increased density, and is loaded with urates. The quantity of urea is diminished, and blood and bile-pigment may be present. The ending of the affection is marked by drowsiness, delirium, convulsions, and coma, death resulting from toxemia, exhaustion, hemorrhage, or similar conditions. In *hypertrophic cirrhosis*, jaundice is an early and persistent symptom. Congestion of the digestive tract, enlargement of the spleen, hemorrhoids, and ascites are absent or present only in mild degrees. The liver is permanently enlarged, smooth, tender, and the seat of paroxysms of pain. The urine is bile-stained and the percentage of urea is normal. Blood is absent. The feces may be devoid of bile-pigment or may be normal. The red blood cells are diminished about one-half, and there is a relative increase in the leukocytes. This form of the affection is more rapid than the preceding, terminating with acute toxemic symptoms in death, usually in one or two years.

Treatment: "The diet should be restricted to milk and similar unirritating food. Fatty and saccharine substances should be eliminated. Alcoholic individuals should be advised to cease drinking. The gastrointestinal catarrh should receive symptomatic treatment. Bichloride of mercury, sodium phosphate, and potassium iodide are highly recommended. The portal congestion is best relieved by salines. The abdominal dropsy or ascites will require the administration of saline purgatives and diuretics. A half ounce of a concentrated solution of magnesium sulphate taken daily before breakfast is of value, as is also the pill containing 1 gr. each of calomel, digitalis, and squill when given after each meal. Acetate of potassium may also be used. Tapping is necessary when these measures fail.

"*Surgical treatment*, with a view to establishing an anastomosis between the portal and systemic circulation, has been employed; but it should never be considered in the presence of complicating renal or cardiac disease."—(Hughes' *Practice of Medicine*).

10. ACUTE GASTRITIS. *Etiology:* "It may arise from overloading the stomach, or from the presence in the stomach of undigested or indigestible foods, alcoholic beverages in excess, irritating medicines, such as the

bromides, iodides, and arsenic, and corrosive poisons such as the mineral acids, corrosive sublimate, copper, carbolic acid, etc. It may also be due to exposure to cold and wet and the infectious fevers.

Treatment: "The stomach should be placed at rest. When the stomach is overloaded ipecac should be given by the mouth or apomorphine hydrochloride, gr. ⅛, should be administered hypodermically. If vomiting has already begun large draughts of hot water should be given. Active purgation by calomel, gr. v to x and sodium bicarbonate, gr. v followed by an ounce of magnesium sulphate or a full dose of Hunyadi Janos water, is of great value in most cases. Fractional doses of calomel are sometimes preferred. After the stomach and bowels have been thoroughly emptied, feeding should be resumed, beginning with the most bland food. Nux vomica, pepsin, or papoid may then be administered."—(Hughes' *Practice of Medicine*).

OBSTETRICS

1. The *true pelvis* is bounded *above* by a plane passing through the iliopectineal line; in *front* by the pubic bones and the obturator membrane; *behind* by the concavity of the sacrum; *laterally* by the obturator membrane, the sacrosciatic ligaments and the internal surface of the acetabulum.

The *brim* is the edge of the superior strait of the pelvis.

The *false pelvis* is that part of the pelvis situated above the superior strait.

The *conjugate diameter* of the *inlet* of the pelvis is a line drawn down the middle of the sacral promontory to the top of the symphysis pubis. It is about four inches in length. The *transverse diameter* of the *inlet* of the pelvis is a line drawn right across the pelvis from one lateral margin of the brim to the other. It is about five inches in length. The conjugate diameter of the outlet of the pelvis is a line drawn from the tip of the coccyx to the lower surface of the symphysis pubis. It is about five inches in length. The *transverse diameter* of the *outlet* of the pelvis is a line extending across the pelvis from one tuberosity of the ischium to the other. It is about four inches in length.

The diameters and measurements of the female pelvis are easily remembered from the following table:

	ANTERO-POSTERIOR.	OBLIQUE.	TRANVERSE
Brim.....	4 inches.	4½ inches.	5 inches.
Mid-plane.....	4½ inches.	4½ inches.	4½ inches.
Outlet.....	5 inches.	4½ inches.	4 inches.

2. The *umbilical cord.*—"At term the cord has been compared to a 'twisted rope of tissues,' extending from the placenta to the child. The cord is of a glistening grayish-white color, of varying thickness, and is usually about 22 inches long, but may be either much longer or shorter. In structure the cord consists of a covering of epithelium continuous with that of the amnion, which surrounds a jelly-like matrix called Wharton's jelly. This consists of mucin, branched corpuscles, and embryonic connective-tissue cells. Within this substance the two arteries and one vein run in a spiral course, usually from left to right; it is to the fact that the growth in length of the vessels exceeds that of the rest of the cord that the twisted appearance of the latter is probably due."—(Jewett's *Practice of Obstetrics*).

3. (*a*) *Adherent placenta* is probably due to some diseased condition of the endometrium, resulting in inflammation of the decidua or placenta. The diseased condition probably antedates pregnancy. There may be partial absence of the decidua serotina, so that the chorionic villi are in direct contact with the uterine muscle.

(*b*) *Treatment of adherent placenta:* "A finger—one or two—must be insinuated between the uterus and placenta at some point already partially separated, or, if no partial separation exist, at a point where the placental border is thick, and then passed to and fro transversely through the uteroplacental junction, acting like a sort of blunt paper knife, until separation be complete. Another mode is to find or make a margin of separation as before, and then peel up the placenta with the finger-ends, rolling the separated portion toward the palm of the hand upon the surface of the still adherent part. Great care is necessary to avoid peeling up an oblique layer of uterine muscular fiber, which might split deeper and deeper until leading the finger-ends through the uterine wall into the peritoneal cavity. Should such a splitting begin, leave it alone and recommence the separation at some other point on the placental margin. It is sometimes only possible to get the placenta away in pieces. These should be afterward put together and examined to indicate what remnants are left behind. It may be quite impracticable to get out every bit, but small remnants or thin layers too firmly adherent for removal do not distend the womb enough to create hemorrhage from their bulk, and the subsequent danger of septicemia from their decomposition may be obviated by injecting warm (2 per cent.) creolin water into the uterus twice daily until everything has come away." (King's *Obstetrics.*)

4. "*The treatment of puerperal sepsis* is both local and general. Locally a thorough disinfection of the whole genital canal is called for in every case. It may appear unnecessary, and may prove, on actual experience, to be even harmful, but no one can tell beforehand how necessary this procedure is. In the vast majority of cases it is productive of the greatest good. It is only occasionally useless, and vary rarely actually harmful. It should precede all other treatment for puerperal infection. The method of disinfecting the genital canal may be described as follows: A double tenaculum, a large, dull curette, a placental forceps, and an intrauterine catheter are boiled for fifteen minutes. The operator disinfects his hands and arms and wears sterile gloves. The patient is placed in the dorsal posture across the bed, with her buttocks resting on a rubber pad. The external genitalia and the vagina are scrubbed with tincture of green soap and pledgets of cotton; the vagina is douched with a sublimate solution, 1:2000. The operator then seizes the anterior lip of the cervix with a tenaculum. An intrauterine douche of sterile water, at least a quart, is administered. Then, with the placental forceps, and, if necessary, with a dull curette, the uterine walls are gone over thoroughly but lightly in all directions, six to twelve times, until nothing is brought away but bright blood. A second intrauterine douche concludes the treatment. If the womb is flabby and large, with a tendency to flexion, so that the drainage of the uterine cavity is not good, it is advisable to pack it with iodoform or sterile gauze. In addition to cleansing the uterine cavity, false membranes or areas of inflammation and localized infection on the cervix or vagina should be treated by the application of a solution of nitrate of silver, a dram to the ounce. It may be necessary to repeat the intrauterine douches several times—in fact, several times a day for many days; in this case plain sterile water only should be used. The general treatment is stimulating. The patient should have as much food of an easily digestible character, chiefly milk, as she can assimilate, and as much alcohol as she can consume, without showing the physiological effects of it. Digitalis is useful as long as the pulse is above 110. Strychnine may be combined with it in suitable cases. To tide the patient over emergencies, carbonate of ammonium in large doses, by the bowels, and nitroglycerin, hypodermically, may be required. Inhalations of oxygen may be of service. Absolute rest and freedom from all disturbances, mental and physical, must be insisted upon, and the patient should be given the best nursing that the family can afford." (Hirst's *Obstetrics.*)

5. *Breech presentation.* Abdominal palpation reveals the head above, which is round, hard, and freely movable; the breech below, soft and irregular in outline. The heart-sounds are heard above the umbilicus. Vaginal examination shows a high position of the presenting part; after dilatation of the os the characteristic features of the breech may be detected—the sacrum and coccyx, the external genitalia and anus, the nates and thighs. There is usually evacuation of meconium.

Vertex presentation. Abdominal palpation reveals the breech above, which is less mobile, not so hard as the head. The heart sounds are generally below the umbilicus. Vaginal examination shows a smooth, rounded tumor at the brim or in the pelvic cavity, and the sutures and fontanelles can be recognized.

L. O. A.: Abdominal palpation reveals the child's back to the left; the extremities above and to the right; the head below. The heart-sounds are most distinctly heard to the left and below the umbilicus. Vaginal examination detects the sagittal suture in the right oblique diameter of the pelvis; the small fontanelle looking toward the left acetabulum.

R. O. A.: Abdominal palpation reveals the child's back to the right; the extremities above and to the left; the head below. The heart-sounds are most distinctly heard to the right and below the umbilicus. Vaginal examination detects the sagittal suture in the left oblique diameter of the pelvis; the small fontanelle looking toward the right acetabulum.

6. *Conditions that justify the induction of premature labor:* (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head. The methods that may be employed are: Partial dilatation of the cervix and the introduction within the cervix (and vagina) of a tamponade of sterile gauze; (2) dilatation of the cervix; (3) puncturing the membranes; (4) introduction of a soft rubber bougie into the uterus; (5) intrauterine injection of glycerine, water, or some other fluid.

7. *Method of performing premature labor: "Catheterization of the uterus:* The first step consists in separation of the membranes from the lower uterine segment by means of a uterine sound or with the finger. The operation must be aseptic. Detachment of the membranes with the sound may be done with the woman in either the left lateral or dorsal recumbent position. For the use of the hand the dorsal position is best. The second step consists in the insertion of one or more No. 12 English bougies, or a sterile rectal tube, between the membranes and the uterus. No anesthetic is required.

Usually the bougie or rectal tube is most readily passed with the aid of the Sims position, the Sims speculum exposing the cervix, which is drawn forward and held with a volsella. The bougie is sterilized by boiling or steaming, the proximal end is cut off, and a stylet inserted. To facilitate introduction the bougie is bent to nearly a right angle at about three inches from the distal end, giving it a large curve. Great care must be used to avoid rupturing the membranes. The instrument is then pushed up gently and in the direction in which it passes most easily. After it has entered between the membranes and the uterine wall, the stylet is drawn down about one inch. The flexible tip of the bougie finds its way readily with little risk of perforating the membranes. The bougie fully in place, the stylet is withdrawn. A second bougie may be inserted if it can be pushed into place without too much difficulty. Bleeding is probable evidence that the instrument has passed behind the placenta. The hemorrhage may occasionally be excessive. It is then best to withdraw the instrument and pass it in another direction. A light tampon of gauze may be packed in the vagina, but it is not required to support the bougie. The instrument is left to be expelled with the child. Labor usually is established within twenty-four hours. This method is not suited to cases in which immediate delivery is called for." (Polak's *Obstetrics.*)

8. *Accidents which may occur to the mother during first stage of labor:* Eclampsia; prolonged labor; rupture of uterus. *During second stage:* Hemorrhage; placenta prævia; laceration of cervix, vagina, perineum, or uterus; premature separation of placenta; rupture of uterus; inversion of uterus; vaginal fistulæ; eclampsia; sepsis; sudden death. *During third stage:* Subinvolution of uterus; postpartum hemorrhage; eclampsia; sudden death; sepsis.

Accidents which may occur to the child: Prolapse of cord; rupture of cord; asphyxia; death; ophthalmia neonatorum, or other septic condition; paralysis; dislocation; hematoma.

9. *Craniotomy.* "The operation may be indicated upon a dead or upon a living child. In the former case the indications for the operation may be comparatively trivial. If the mother can be saved any additional risk or suffering by the rapid delivery of the mutilated child, craniotomy is not only justifiable, but advisable. In case of prolapse of the umbilical cord, with a contracted pelvis, the commonest condition that calls for craniotomy upon a dead infant, it is far better to open the head and to deliver the child easily with a craniocast than to apply the forceps to the head at the superior strait and to subject the mother to the delay, pain, and danger of a prolonged forceps operation, when nothing is to be gained by it.

Craniotomy upon the living child is only justifiable in exceptional circumstances. To condemn this operation, however, unreservedly and without exception is a mistake. In cases of difficult labor, if the pelvis is contracted or the child overgrown, and the physician must make a choice between cesarean section, pubiotomy, or craniotomy, if he has no skill in surgical work and is unable to procure expert assistance, it is better, unquestionably, to sacrifice the child for the mother's sake, rather than to attempt a serious surgical operation, amid unfavorable surroundings, and performed by an unskillful operator whose mortality must be very great.

"Every attempt must be made to avoid the destruction of a living child, of course; and if the operator feels himself possessed of sufficient skill to attempt the more serious operations of cesarean section or pubiotomy with fair prospect of success, or if he can summon to his aid an expert surgeon, he should not think of performing craniotomy upon the living child."

The operation: "The woman should be anesthetized and placed in the lithotomy position, and brought well to the edge of the bed or table. The child's scalp is seized by a strong volsella forceps, which is handed to an assistant, who pulls upon the instrument firmly, so as to fix the head at the superior strait. The operator then inserts two fingers of his left hand and feels for a suture or a fontanelle. The perforator is inserted into the vagina, along the palmar surface of the fingers, and is plunged into the skull at a point upon which the finger-tips rest—that is, through a fontanelle or suture. When it has entered the skull the perforator is twisted about in all directions, in order to break up the brain, and is also opened in several different directions to enlarge the opening in the skull. The large catheter is next inserted and attached to a syringe. A column of water is injected into the cranial cavity to wash out the remaining brain substance. Next, if necessary, the size of the emptied head may be reduced with a cephalotribe.

This is only called for in case of extreme pelvic contraction or in the presence of some pelvic tumor seriously diminishing the capacity of the pelvic canal. In the majority of cases a craniocast may be used instead of the cephalotribe. The internal branch of this instrument is inserted within the skull. The outer branch is next introduced in the same manner that one would insert a blade of the forceps. The two branches are then locked, and the handles are screwed firmly together, care being taken that the internal branch is inserted deeply within the cranial cavity, so that it shall get a firm grasp upon the skull. The child is now extracted in the same manner that one would extract the head with the forceps, except that the tractive efforts are made uninterruptedly and with greater force. In certain cases it is sufficient simply to perforate the skull. This applies particularly to cases of hydrocephalus.

The head being evacuated, the forces of nature are sufficient to insure the child's delivery. If it is necessary to perforate the aftercoming head, the perforator may be inserted behind the ear, in the lambdoid suture, under the chin, through the roof of the mouth, or, possibly, through the foramen magnum. In a case of hydrocephalus with breech presentation, should there be great difficulty in reaching the aftercoming head, it is possible to evacuate the fluid by perforating the spinal column and passing a catheter through the spinal canal into the cranium." (Hirst's *Obstetrics.*)

10. *Pituitrin* is an extract from the posterior lobe of the pituitary gland; it may be given cautiously in cases of uterine inertia. As it may cause very severe uterine contractions, it should not be given unless the os is dilated and there is no obstruction to delivery. It is best administered intramuscularly in the gluteal region in doses of 1 c.c., which may be given two or three times at intervals of half an hour. Its use is not without danger.

(*To be concluded.*)

TUBERCULOSIS: ITS DIAGNOSIS AND TREATMENT WITH THE ROENTGEN RAY.

By A. R. McMICHAEL, A.M., M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE IN THE NEW YORK HOMEOPATHIC MEDICAL COLLEGE AND FLOWER HOSPITAL.

SINCE the discovery by Koch in 1882 of the tubercle bacillus when it was proclaimed to the world that the cause of the "white plague" had been found, tuberculosis, as a center of study and experiment, has stirred the imagination of the medical profession to intense activity with the hope that at last a remedy might be found that would overcome the disease which has placed to its discredit the death of one in every seven of the human race; and although one-third of a century has passed since that discovery, comparatively little has been accomplished in checking the progress of the infection.

In reviewing the history of the endeavor to find a means for the complete elimination of this scourge, we are impressed with one factor which stands out more prominently than all others, indicating a distinct advance in the direction of ultimate success.

Our greatest handicap in dealing with tuberculosis has been the difficulty in diagnosing the disease in its early stage; that is to say, before extensive involvement and degenerative processes are so pronounced that toxemia overwhelms the patient ere the remedial measures at our command become effective. For that reason, our efforts in the past were largely doomed to failure. But with the *x*-ray, used both as a diagnostic agent and as a remedial means, we are to-day in possession of the most valuable aid thus far known in overcoming tuberculous infection.

So much has been written and so many diverse opinions have been stated in regard to the value of the *x*-ray as a means of diagnosis that confusion and distrust abound. It is evident from the reading of recent literature that differences of opinion on the subject are in some degree owing to the faulty interpretations arising from a study of the flat plate. It is true that in advanced conditions the single plate may show evidence sufficiently positive for a diagnosis; but it is not the advanced condition that is important; were this true, physical signs would be all-sufficient for a diagnosis without the aid of the *x*-ray.

With the flat plate radiograph in the early stages of the disease, the evidence cannot be positive, even though the radiographer be faultless in his work and the single picture is well backed up by clinical history. But the use of stereoscopic plates has clearly demonstrated that no one is justified in making a diagnosis of incipient tuberculosis without their aid.

Physical signs, even in the first stage cases where infiltration can be detected by percussion, fremitus, or whispered voice, are less positive in this evidence than the stereoscopic plates, not only as to the extent of infiltration, but more important as showing the location of the original focus, whether it be in the hilus, in the apex, or in the pleura.

The unreliability of physical technique even by experts, in this field, is so well known that it would be difficult to find two technicians of unquestioned ability who fully agree as to their findings in incipient cases, while with the stereoscopic plates, plus clinical history and physical signs, we more closely approximate the positive than by any other method of diagnosis.

If the disease has reached a stage where a positive diagnosis can be made by physical signs, we are already face to face with a malady where loss of time has become a deterrent factor in the early establishment of repair.

It is a well-established fact that in caseous tuberculosis, on account of the virulent strain of the tubercle bacilli and the rapid development of degenerative processes in the tissue, an early diagnosis becomes a most valuable asset in the treatment and unless we can begin our treatment before large areas are involved, the rapid development of toxins overcomes the patient, without even a protest of a remedial nature.

Another reason for an early diagnosis is the value of positive evidence of infection, though this evidence be a healed lesion in a quiescent state. If we are to prevent reinfections later in life, we must insure the patient's escape by overcoming the tubercle bacillus before resistance is lowered in the adult, or the intenser activity is ushered in, resulting in an open tuberculosis which becomes the cause of infection in children in a greater number of cases than any other factor; and it is only reasonable to assume that if we could control the disease before the resistance is lowered, or this activity takes place, it would go a long way toward universal prophylaxis.

So much time and thought have been given to the question of healed tuberculosis, latent infection, and immunity following early stages of the disease, that we have grown to feel unduly secure; and thus, after the initial stage has become quiescent, we too often assume that the future will be safe if sufficient food, sleep and rest are provided; in a word, if

proper hygienic conditions, avoidance of dissipation, etc., are maintained. Indeed, if we can be sure of an ideal mode of living for the patient, all will be well, and no one can ignore the importance of "the simple life" as an aid in thwarting any infectious process; but how many are going to heed the wisely given advice? Knowing that "to err is human," can we rely on a system of education as a prophylaxis for such a scourge?

It is a well-known fact that tuberculosis is primarily an infection of childhood; that 90 per cent of infections occur before the fifteenth year of life; and that 50 to 70 per cent. of these infections occur before the fifth year; consequently the problem which confronts us to-day is the treatment after infection has become manifest.

"The observation of Bloss, who followed 160 cases of tuberculosis of the lymphatic glands from Czerny's Clinic in Heidelberg during a period of from three to twelve years determined that 40 per cent of the subjects developed pulmonary tuberculosis." (Pottenger: "Clinical Tuberculosis.")

"Aufrecht in an examination of tonsils found that 20 per cent contained tubercle bacilli and 19 per cent of adenoids were involved."

"Dieulafoy extirpated 61 hypertrophied tonsils and he injected a preparation of them into guinea pigs, with the result that 13 per cent of the pigs were infected."

"In the first examination made by the officers of the Federal Meat Inspection Service (from the report of which I quote) the superior cervical glands were nearly always affected. At the postmortem examination held by bureau inspectors, over a consecutive period on 120,000 tuberculosis hog carcasses, 93 per cent were found to contain lesions of these glands."

"In the cattle, they found the lesions of tuberculosis were located in the cervical glands of 66 per cent, in the bronchial glands 54 per cent and in the mediastinal glands 63 per cent of the cases examined."*

From the foregoing we are impressed with the fact that the lymphatic system plays a very important rôle in the development of tuberculosis. It is during the child's early years that the lymphatic system is most active; and the location of the lymphatic glands is such as to give protection to the body as an outer defence.

In consideration of the fact that the tonsils and adenoid tissue frequently are the first points of infection in the child, are we not justified in assuming that the susceptibility of the child is dependent largely on the pathological state of these organs?

Normal lymphatic tissue in itself has resisting power which becomes vitiated by frequent and prolonged inflammatory changes. These changes must be recognized in order to be corrected so that the natural protection to the child may be maintained. But the unnecessary sacrifice of these organs removes the first line of defense, which nature has provided, so important to the resisting power of childhood.

The diagnosis of early tuberculous disease depends largely on the clinician's viewpoint rather than on that of the pathologist. Starting with the fact that sooner or later virtually all human beings are infected, the interest of the clinician centers largely on the early constitutional symptoms of infection; these effects are so subtle and varied that the average physician is inclined to underestimate their importance until physical signs reveal the far advanced disease as first discovered in the lung; and while the prognosis in this stage may be fairly favorable, depending largely on its form of development and constitutional dycrasia, nevertheless our greatest hope for the complete eradication of the "white plague" must necessarily depend on our recognition of it during its inception.

Children suffering from tuberculous infection, which is subject to frequent states of activity, often suffer from general malnutrition; they are stunted in growth; they show lack of endurance and a failure to develop in a normal manner. They may be bright mentally, even precocious, but they lack both physical and nervous endurance.

Loss of weight, or failure to gain weight, is shown early; although the child may have a ravenous appetite, there is defective assimilation; and it grows thinner daily; or there may be great loss of appetite—no desire to complete the ordinary meal; and even the small quantity of food taken often produces indigestion which may be followed by nausea, vomiting and diarrhea.

When these disturbances are not directly traceable to improper food, colds, or the ordinary infections of childhood, our suspicions should be aroused; particularly so if an intermittent temperature accompanies the other symptoms.

With a constitutional disturbance of this character, we should be on the lookout for glandular involvement, either in the tonsils, the cervical or the bronchial glands.

If we are still in doubt as to whether or not we are dealing with a tuberculous infection, a positive von Pirquet will give us evidence on which we are justified in making a tentative diagnosis.

Radiography, while it does not invariably tell us whether we are dealing with an active or a latent infection, does show calcified tubercles if present; and, in my opinion, a calcified tubercle in its quiescent state should be considered important, not only on account of the positive evidence of infection, but more important still from the therapeutic considerations.

A latent tuberculosis of the glands may be the center at any time of an active process; and it should be dealt with while in its active state in order that the future of the patient may remain safe.

While I am conscious of the fact that early tuberculous infections may have an immunizing effect on the organism and thus possibly prevent the development of phthisis later in life, nevertheless, many cases do become active through vicious environment and lowered resistance; and though the percentage of reinfections may be small, we have no right to ignore, however slightly, the possibilities of an infection carrying such evil import.

As an evidence of secondary infection, or rather a flaring up of a smouldering fire from the calcified glands, the *x*-ray shows in many cases the hilus thickened with caseous deposits; and from these foci frequently appears an extension of the affected area to the parenchyma of the lung, more often to

*Dieulafoy: *Bulletin de l'Académie de Médecine*, 1895, Nos. 17-20. Bloss: Mitteilungen aus den Grenzgebeiten der Medizin und Chirurgie, 1899.

the apex, which becomes an additional center of infiltration.

The fan-like extension from the hilus to the periphery is considered by some of our best Roentgenologists as positive evidence that the primary foci are found at the roots of the lung, rather than at the apex; and, although the radiograph does not give us any clue as to when these glands became involved, we have presumptive evidence that the infection occurred during childhood.

Consequently, concealed or clinically inactive cases of tuberculosis call for active measures rather than "watchful waiting" for an evil day when the body is less resistant.

The final consideration, and to me the most important, as an aid to the complete control of this scourge, lies in the use of the *x*-ray, not only on account of its diagnostic value, but more especially on account of its importance as a therapeutic factor.

The earliest recognition of its use in this respect dates back to the early history of this wonderful agent in the field of therapeutics. My first experience with it began in 1899; at that time a few reports had been published showing unquestionably its effect in overcoming tuberculous adenitis. I was early impressed with those reports on account of a boy 14 years of age under my care with a tuberculous mass in the cervical region, whose mother, at that time, was dying of pulmonary tuberculosis, and I decided to test the value of the *x*-ray in this case. The affected glands had been enlarged for over two years and several had coalesced into an enormous mass.

Treatments were given three times a week; at the end of two months the enlarged mass had entirely disappeared. This boy has since married, and he is the father of several children. No further evidence has appeared of his early infection. Since that time so many cases have been reported that today the *x*-ray may be considered practically a specific in this variety of tuberculous infection.

During the past three years while treating cases of tuberculous adenitis with the *x*-ray, I have been impressed with its therapeutic power over tonsillar and adenoid involvement; but up to this time, so far as I am aware, no reference to its action on these glands has been published. In three cases of cervical adenitis under my care I found very large tonsils and adenoids; all these had been treated by other physicians who had advised removal. In one of the three, the tonsils and adenoids were so large that the child's mental and physical development had been retarded.

It was while treating the cervical enlargement that an improvement in the breathing of the one child was noticeable; also the mental and physical disturbances became less evident. An examination of the throat showed a marked improvement in the size and the character of the tonsil itself. The spongy gland, with numerous pockets, had undergone a distinct change; and at the end of the treatment of the cervical glands, the tonsils and adenoids in all three had assumed a normal aspect. The improvement in each one of these cases was not confined to the glands alone, but it was more marked still in the constitutional change.

The tendency to frequent colds, which was marked in all, practically disappeared; and a general improvement in every part showing underdevelopment soon became obvious.

I am convinced, from the results in these three cases and of many others since, that we have in the *x*-ray a therapeutic power potent in many cases to relieve one of the commonest affections of childhood, at the same time destroying tuberculous infection in these glands without robbing the child of a part of its natural inheritance and defense.

An important question in this interesting subject is—What are we going to do with the 1,000,000 patients in this country who are already far enough advanced in the disease to leave little doubt as to the correctness of the diagnosis? How many of this vast army of suffering humanity can be restored to health and made immune from further infection? The answer involves so many phases of the subject that we become bewildered and at the same time, fascinated with its possibilities.

Some years since, a systematic campaign was undertaken in this country to eliminate the "white plague." The results of this undertaking are given in a report recently issued by the Bureau of Public Health Education. I quote from the report: "A period of apathy has followed the tremendous enthusiasm evoked by the antituberculosis campaign conducted some ten years ago. Despite the strenuous work of these ten years, the annual expenditure of hundreds of thousands of dollars, one-seventh of all persons who die, die because of tuberculosis infection. In the city of New York the deaths from all forms of tuberculosis have varied but little from 10,000 a year since 1905. At the present time there are 35,000 recognized cases of pulmonary tuberculosis in this city, and only 10 per cent. of these are under the care of private physicians." From the foregoing we are impressed with the fact that 90 per cent. have been cared for through the benevolence of the public in hospital and sanitarium. The period of apathy was a natural sequence to the enormous energy put forth and the large amount of money spent with the meager results shown.

The National Tuberculosis Association is to-day seriously considering the question of enlarging the hospital and sanitarium facilities, co-operating with the Federal Reserve Board to meet the requirements of a large increase of tuberculosis cases resulting from the war. Judging from the report given above, little may be expected from this source in the stamping out of the plague, no matter how conscientious the endeavors nor how much money is spent to that end.

For several years experiments have been going on with the *x*-ray, not only as means of diagnosis, but also as a therapeutic aid, with varying degrees of success. Some have recognized its potential power as a therapeutic agent, but they have failed to impress the profession at large with the value of its universal adoption.

In the résumé of cases which I have chosen to report, are represented the most serious classes of tuberculosis, as well as the latent or quiescent forms of the infection, showing the power of the *x*-ray as a prophylactic as well as a curative agent in overcoming the disease in all its varied aspects, even in advanced and rapidly degenerative processes with cavitation.

Case I.—*Latent or Healed Tuberculosis.*—G. K., age 18. *Family History:* Mother died of tuberculosis at

Davos, Switzerland, twelve years ago. Uncle died of tuberculosis at thirty years of age.

Patient's History: Never developed normally either mentally or physically, grew rapidly; height 6 feet 3 inches. Always thin, pale, anemic and tired, no ambition. Enormous appetite, yet emaciated. Eats all kinds of food, except fats. Craves meat three times a day in large quantities. Has had frequent colds, but never suffered from bronchitis, pneumonia, pleurisy, whooping cough or measles. Temperature normal, respiration normal, pulse 94. No cough. Volunteered for service when war was declared, but was refused after a physical examination on account of a tuberculous right elbow and slight involvement of the right apex, discovered by physical signs. Patient came under my care in May, 1917. A physical examination confirmed the previous report. The right elbow was one-third larger than the left, without pain, but with restricted motion and stiffness.

Stereoscopic plates made of the lungs showed the normal markings distinctly. There is diminished aeration of both upper lobes, more marked in the left. The diaphragm is normal. The heart is normal in size, shape and position. There is thickening along both roots extending up along the branches of the left ascending bronchus. There is evidence of infiltration in both upper lobes, more pronounced in the right. Numerous calcified tubercles are in evidence scattered over both lungs. Extremely narrow intercostal spaces are shown as an evidence of superficial respiratory action.

Treatment with the Roentgen ray and high-frequency auto-condensation was begun in May with daily exposures over the lungs as well as over the elbow. Four months later a second pair of stereoscopic plates were made showing the following changes: The normal markings of the lungs are shown distinctly. Both upper lobes show normal aeration. Thickening of the roots diminished; no extension up along the branches of the bronchus. No evidence of infiltration. No calcified tubercles to be found. The intercostal spaces normal, showing a normal respiratory action.

The circumference of the right elbow is one inch greater than the left. The development of the patient in general has been most marked in every way—posture is erect; color normal, digestion good. He has gained twenty pounds in weignt—is ambitious and does not tire easily.

Case II.—*Fibroid Phthisis.*—Mrs. S., age 34. *Family History:* Several members of the family died of tuberculosis.

Patient's History: Had measles and whooping cough when a child. Five years ago suffered from pleuro-pneumonia of left lung; was confined to the bed during two months, which left her with a persistent cough. After four years of treatment by her family physician she was sent to Liberty Sanitarium, New York, where she remained one year, gradually failing in strength and weight.

Her story as told by herself is virtually as follows: On arriving at the Sanitarium, weight was 113 pounds, a loss of 16 pounds since an attack of pneumonia. While in the Sanitarium her weight gradually fell until it reached 94 pounds. At this time, the attending physician advised her to return to her home and spend the last two or three weeks of her life with her husband and children. After returning home she was advised to consult the writer. An examination showed the left lung completely involved with a large cavity in the apex. The right apex showed infiltration down to the third rib, anteriorly. Sputum contained numerous tubercle bacilli.

Treatment with *x*-ray and high-frequency autocondensation was given three times a week, the patient coming from her home in Brooklyn by trolley in all kinds of weather during the entire winter. Improvement began immediately and progressed so rapidly that at the end of four weeks she had gained 18 pounds in weight. Cough and expectoration were less; appetite, color and general condition showed marked improvement.

The treatment was continued six months, when she was discharged entirely well. Sputum examination was negative, cough and expectoration absent. No râles were heard in any part of the lungs. Weight 153 pounds, 20 pounds more than she had ever weighed before. During her treatment she became pregnant, and when the child was born it weighed more and looked healthier than any of her previous children at birth. No further trouble with her lungs was experienced. This patient, three years later, went violently insane, and she died in an asylum; a history of insanity ran through three generations.

Case III.—*Caseous Tuberculosis* (Galloping Consumption).—A. S., age 14. *Family History:* Good.

Patient's History: Had the usual diseases of childhood, including whooping cough and measles. Was always considered an unusually healthy boy. In November, 1907, he suddenly developed a cough, accompanied by an afternoon temperature running from 104° to 105.5°, with rapid loss of flesh. One month after the onset of his trouble his weight was 84 pounds, having dropped from 128 pounds.

At this time he came under my care. Physical examination revealed an active process which had involved the entire left upper lobe. Percussion dull over entire lobe, bronchial breathing; fremitus and crepitant râles —all pronounced. Temperature in morning up to 1 P.M. 99°, pulse 102, respiration 32. Afternoon temperature gradually rose until it reached 105.5° at 7 o'clock, pulse 128, respirations 36. Sputum filled with tubercle bacilli.

Treatment with the *x*-ray and high-frequency autocondensation was given daily. Improvement began immediately; at the end of four weeks the patient had gained twenty pounds, temperature was normal, pulse 104, respiration 24. Cough and expectoration much less. Appetite good—in addition to his regular meals he was able to take the whites of eight eggs a day with four glasses of milk.

Physical examination showed a marked improvement. Auscultation found numerous râles; tubular breathing slight; fremitus less; percussion still dull. Treatment was continued three months, when the patient was discharged cured. Sputum negative; cough entirely gone; all physical signs normal. Six months after beginning treatment patient weighed 145 pounds, 17 pounds more than he had ever weighed before. No further trouble with his lungs has been experienced, now eleven years since.

Case IV.—*Fibro-Caseous Tuberculosis of the Lungs.* —Mr. R., age 42, Feb. 13, 1916. *Family History:* Good.

Patient's History: Patient had pneumonia of left lung ten years ago, since that time has coughed more or less continually, especially mornings. Three months ago he began having an afternoon temperature ranging from 100° to 105°, with severe coughing spells, worse in the cold air and still worse on lying down and at rising in the morning. Expectoration yellow and at times streaked with blood. Voice hoarse. Weight 153 pounds.

Auscultation found numerous râles over the roots of the left lung along the spine. Percussion over left apex dull with increased vocal fremitus. Whispered voice marked over apex, also over hilus.

Roentgen diagnosis by Dr. Lewis G. Cole follows: "Stereoscopic and plain roentgenograms of the chest show distinctly the normal markings of the lungs. There is diminished aeration of both upper lobes. The diaphragm is normal; the heart is normal in size, shape and position; a thickening of the mediastinum somewhat obscures the arch of the aorta. There is increased density around the roots of the lungs, and extending out along the branches of the bronchi, and involving both apices. There is an infiltration of both apices, more marked on the left side than on the right. The process has not gone to the stage of consolidation, but the infiltration is very extensive. I believe the case is one that demands radical treatment to check the extension of the process." In answer to my question as to what he meant by "radical treatment," Dr. Cole answered, "Mountain air and sanatorium treatment."

An examination of sputum by Dr. Heitzman showed 15 tubercle bacilli per field.

Treatment by *x*-ray and high-frequency electricity was begun on February 13th, and continued daily. Fourteen days after beginning treatment, temperature was normal and has remained so. Patient had improved in every way. Cough and expectoration were gradually reduced, weight increased. Color better, ap-

petite improved. At the end of two months an examination of sputum did not show any tubercle bacilli. No râles were found on auscultation. Cough slight.

At the end of four months from the beginning of treatment, another Roentgen examination of the lungs was made by Dr. Cole, who reported to me the following: "Roentgen findings: The normal markings of the lungs show distinctly. There is diminished aeration of both the upper lobes. The diaphragm is normal and the heart is vertical. The arch of the aorta is slightly thickened. There is a thickening along both roots extending up along the branches of the right ascending bronchus. Both apices are involved. There is evidence of infiltration of both upper lobes. The area in the left apex shows more evidence of fibrinization and less evidence of exudation than was present when the first examination was made. From a study of these plates and from a comparison with those made previously, I feel that I am justified in stating that I find no evidence of an extension of the tuberculous process and the fibrinization suggests that the process has been checked."

An examination of a small exudate which the patient was able to get from clearing his throat did not show any tubercle bacilli. The cough having entirely ceased and his weight increased, he told me he weighed twenty-three pounds more than he had ever weighed. The patient expressed himself as being mentally and physically in as good condition as he had ever been in his life; he was discharged and has not shown any further trouble with his lungs.

Case V.—*Tuberculous Peritonitis with Ascites.*—Catherine N., age 17. Referred to the tuberculosis clinic May 5, 1916. *Family History:* Father died of tuberculosis, age 52. Father's mother died of tuberculosis. Mother living and well; one brother died in infancy of spinal meningitis. Two brothers and one sister died of pneumonia during childhood.

Patient's History: Had measles during childhood. At 15, menses developed normally and continued regular in time and character. At 16 suffered from the grip, which lasted one week, leaving her much prostrated, with a loss of eight pounds in weight. Three months ago menses stopped, followed by profuse night-sweats and accompanied by pain over entire abdomen, worse on the right side and worse also on the least pressure which caused nausea and vomiting of bile, great prostration, headache and constant sleepy condition. Abdomen distended.

May 5, patient came under my care. An examination showed the abdomen completely filled with fluid; the patient suffering from great pain over entire abdomen; worse on the least pressure, and great difficulty in breathing. Physical examination of the chest posteriolily revealed marked whispered voice over upper lobe of right lung extending from apex down to the fourth intrathoracic vertebrae. Anterior chest. Whispered voice over upper right lobe from apex down to fifth rib. Heart: No murmurs, pulmonic and aortic second sound accentuated. Temperature 102.6°, pulse 120, respirations 26.

Urine, twenty-four hour specimen, 14 ounces, color yellow, specific gravity 1022, albumin trace, urea 3 per cent., indican 2 plus. Total solids 375 grs. Red blood corpuscles occasional, pus corpuscles few, epithelia, kidney and bladder few.

Blood: Hb 60 per cent.; erethrocytes 4,020,000; leucocytes 8,120, neutrophiles 76 per cent., small lymphocytes 19 per cent.; large lymphocytes 7 per cent. Von Pirquet 4 plus positive. Sputum negative.

A pair of stereoscopic plates made of the chest showed the normal markings of the lungs. There is diminished aeration of the right upper lobe. The diaphragm is displaced upward on both sides. Heart normal. There is thickening of the hilus extending upward along the branches of the right ascending bronchus, with evidence of slight infiltration of the right upper lobe.

Treatment with Roentgen ray began May 5, exposure being made daily over the abdomen as well as the chest. On June 1 patient reported free from pain for the first time since set-back. Night-sweats much less. Vomiting of bile occurred occasionally. Urine had increased from 14 to 40 ounces in twenty-four hours. Abdomen much softer. At this time patient began suffering from diarrhea, with flatulence and indigestion, although the vomiting of bile was less.

Treatments were continued as before. On August 12, the menses reappeared, having been absent six months. Digestion had improved; vomiting had ceased; headache and diarrhea with flatulence had entirely cleared up. Appetite returned and patient began increasing in weight. Abdomen entirely free from fluid. Patient virtually normal in every respect. The second stereoscopic plates did not show any abnormal condition in the chest.

Blood: Hb 85, erethrocytes 4,000,000; leucocytes 8,000, neutrophiles 78.5 per cent., large lymphocytes 6 per cent, small lymphocytes 12.5 per cent., eosinophiles 3 per cent.

Case VI.—*Fibro-Caseous Tuberculosis of the Lungs.*—M. F., stenographer, age 22, came to clinic in September, 1917. *Family History:* Father, mother, five sisters and two brothers all living and well. No history of tuberculosis.

Patient's History: Had measles when five years old, whooping cough when very young. Was always subject to frequent colds, often ending in bronchitis, which was difficult to cure. Appetite always poor. Pale and anemic all her life. Menstruation developed during the eleventh year, regular, bright red flow lasting five days, accompanied by more or less pain. Digestion good, does not like milk or eggs, prefers meat to all other food. Bowels regular. Sleeps well. Not nervous as a rule, but much depressed over present condition. Has had a cough for the past two years which has not responded to any treatment. Cough always worse when lying on the left side; constant tickling in the throat accompanied by hoarseness. No expectoration until one year ago. Sputa grey and frothy. Sleeps nine and ten hours at night with occasional naps during the day. Menses always regular, profuse flow, much prostrated during first two days. No night-sweats, but suffers from profuse perspiration of feet; maximum weight 90 pounds, present weight 85 pounds. Temperature 100.4°, respirations 22, pulse 96.

Physical examination. Right anterior. Percussion dull over right apex down to fourth rib with increased fremitus and marked whispered voice. Numerous räles below clavicle over small area. Left anterior: Percussion dull below clavicle, increased fremitus and whispered voice extending to third rib. Posterior chest: Percussion dull, increased fremitus and marked whispered voice with crepitant râles below seventh cervical down to fourth thoracic vertebra, on both sides of spinal column, more marked on right side.

Sputum, twenty-four hour specimen, showed 40 to 50 tubercle bacilli per field.

Blood: Hb 60 per cent.; erethrocytes 4,140,000; leucocytes 11,700, neutrophiles 86 per cent.; small lymphocytes 105, large lymphocytes 7 per cent. Von Pirquet 3 plus positive. Urine, reaction acid, specific gravity 1022, albumin trace, urea 2.3 per cent., indican normal.

Stereoscopic plates made of the chest show the normal markings of the lungs distinctly. There is diminished aeration of both upper lobes. Marked infiltration on left side below the clavicle with distinct mottling. On the right side below the clavicle two cavities are shown surrounded by fibrous rings.

Treatment with the Roentgen ray was begun on Sept. 21st, and continued daily until Feb. 11th. Physical examination at this time showed an occasional râle in right chest over region occupied by cavities. All other physical signs were modified from first examination as a result of increased fibrosis.

Sputum showed occasional tubercle bacilli. Blood: Hb 80 per cent.; erethrocytes 5,760,000; leucocytes 7,000, neutrophiles 76 per cent., small lymphocytes 12 per cent., large lymphocytes 9 per cent., large mononuclear 1, transitional 2.

Temperature between Sept. 21 and Nov. 30 fluctuated between 99° plus and 101° plus; after Dec. 1 to Feb. 11, temperature did not go above 99° but five times. Respirations during this period ran from 22 to 25; pulse 80 to 120. Weight increased from 85 to 98 pounds. Cough seldom.

Two months later stereoscopic plates made of the chest showed complete fibrosis of diseased areas. Cough entirely gone; râles absent; sputum negative.

Case VII.—*Tuberculosis of the Kidney and Bladder.*—E. V. L., age 42.

Patient's History: Patient always healthy until 1894, when he suffered from an attack of pleuropneumonia. Sick one month. After the attack had apparently subsided he was examined by Dr. Janeway, who found evidence still of non-resolution. In 1900 he had a second attack of pneumonia which kept him in bed for six weeks. This attack was accompanied by high temperature and delirium, followed by slow convalescence. Following these pneumonic disturbances, patient was apparently well until 1912, when, without warning while urinating, a slight hemorrhage occurred, consisting mostly of two or three small clots. Recurring attacks followed on an average of about one a month for six months. Examinations for the tubercle bacilli were made frequently with negative results. Eight months after the first hemorrhage, Dr. Keyes found positive evidence in the urine of tuberculosis; further examination showed that the left kidney was the focus of infection. An operation for removal of the kidney by Dr. Keyes followed. Three weeks after the wound had healed, it reopened. Patient at this time consulted Dr. Osler at Oxford, who advised the sun cure at a sanitarium in Leysin on Lake Geneva, Switzerland, the treatment consisting of exposure to the sun's rays 5 to 10 hours daily and continued from July 10 to Sept. 22. While he was undergoing this treatment an abscess developed in the scrotum which was opened. An examination of the pus showed tubercle bacilli.

On returning to New York, patient was under the care of Dr. Adrian Lambert; six months later an abscess developed in the prostate which opened into the bladder and continued to discharge for six months. At this time, May, 1917, the patient was referred to the writer by Dr. Lambert. The patient's condition at this time, as later described by Dr. Bugbee, who had examined him cystoscopically and had treated him locally, was virtually as follows: The entire bladder was a solid mass of tubercles with numerous tuberculous ulcers over the entire area and, while it was impossible to determine positively whether the remaining kidney was involved or not, owing to the inability to pass a catheter on account of so much swellng at the ureteral opening, in his opinion the kidney was involved. The urine at this time was filled with tubercle bacilli, also a large amount of pus and mucus from the extensive cystitis.

In answer to inquiry regarding Roentgen examination of the lungs, it was stated that Dr. Cole had made radiographs of the chest in 1913 and had reported that, while infection was evident, there was no activity, the findings being a latent or healed process. Consequently, further diagnostic evidence from this source at this time was not considered necessary.

Treatment began with the *x*-ray in May, daily exposures being made over the entire genito-urinary tract. After four months of treatment an examination of the urine, made by several pathologists, did not show tubercle bacilli.

A report from Dr. Adrian Lambert was received Oct. 6th, regarding the physical as well as the urinary examination made at this time follows: "I examined Mr. L. the other day and had his urine gone over. I found that, locally, there was some change in the prostate, not a great deal, but yet some, it was less tender and not as soft. His urine still contained pus, but no bacilli were found."

A cystoscopic examination at this time by Dr. Bugbee was made to determine objectively the condition of the bladder, the result of which showed that the inflammatory condition had entirely disappeared; the ulcers were healed, and instead of the bladder being one solid mass of tubercles, only three pinhead tubercles were found. Treatment was continued as before; one month later, on Nov. 9, a second pair of stereoscopic plates was made of the chest by Dr. Cole, with the following report: "Plates made of the chest show the normal marking of the lungs distinctly. There is diminished aeration of the right apex. The diaphragm is normal. The arch of the aorta is normal. There is definite evidence of infiltration of the extreme right apex. Comparing these plates with the previous ones (1913), I believe that the findings are identical in both degree and character with the findings of the plates in the previous examinations, although I believe that the infiltration of the right apex was not reported in the previous report, although the involvement was present at that time."

The following letter from Dr. Lambert, received Jan. 17, 1918, is interesting and confirmatory of previous examinations: "The guinea pig which was inoculated with the urine of E. V. L. on Nov. 28 was killed six weeks later and no signs of tuberculosis were found anywhere in its body. There were a few white nodules in the spleen, but, on being sectioned, these proved to be chronic inflammation of a non-tuberculous type. The lymph nodes were somewhat enlarged but there were no tubercle bacilli to be found."

In reviewing the history and *x*-ray findings as well as the results of treatment in this case, the following deductions I believe to be justifiable. The report on the stereoscopic plates made in 1913 distinctly showed infection and infiltration, although clinically no evidence of activity was present. In addition there was no evidence of lowered resistance to account for a renewal of the infectious process. In fact, the patient was physically and mentally in sound health, living a perfectly normal life, surrounded by all the comforts that money could give. At the same time a relighting of the early infection became manifest through metastasis.

I believe we have here a good illustration of the danger to an individual, with a healed tuberculous infection, even when he is surrounded by everything in life that could possibly give security against future trouble. *If such a patient is not free from grave possibilities, what can be said of those who are less fortunate?*

In the stereoscopic plates of the lungs many calcified tubercles were shown; consequently, I believe that the original foci of infection were here; and my contention, already stated in the foregoing pages, is that in a remedial agent disposing of these calcified tubercles lies our only security in preventing future activity.

The results of treatment in the foregoing cases show conclusively that we are to-day in possession of a powerful agent which is capable of overcoming tuberculosis in its most active, as well as in its latent and quiescent stages; and at the same time we are able to demonstrate its mode of application so that the medical profession at large can utilize this power in all manifestations of the disease.

Speculation as to the manner in which the *x*-ray exerts its power for good in tubercular troubles as well as in malignant neoplasms has been an interesting one ever since its introduction into the therapeutic field.

It is a well-established fact that the tubercle bacilli exposed to the sun's rays can live but a few hours, while cold, even to the point of freezing, does not inhibit their inherent power for evil. This fact in itself suggests that in *light* we are dealing with a power which is potent in showing at least the first step in the process of cure.

The fact that the *x*-ray is a thousand times more powerful than the sun's rays, and that this power is capable of penetrating the hidden recesses of the body, would suggest that in its use in tuberculosis each patient is constantly setting free within his body bacillary substances producing an autogenous vaccine which is sufficient to inhibit the motility and multiplication of the tubercle bacilli.

In this connection the statement of Pottenger in discussing the value of artificial tuberculin in the treatment of tuberculosis is suggestive; he states: "Could we make our tuberculins from tubercle bacilli

grown upon the tissues of the individual to be treated, and could we make a preparation which would contain all of the various bacillary products in proper proportions, I do not doubt that we could attain a highly immunizing product, but, inasmuch as this has so far proved unattainable, we must realize that our artificial products lack some of the properties which are greatly desired in them." The reasoning set forth so forcibly by Pottenger shows why an autogenous vaccine has therapeutic value in every case, while the artificial product lacks something in its manufacture which would make it a specific in all cases.

We have abundant evidence of the value of the artificial tuberculin in the cure of some cases of tuberculosis; and the question naturally arises, *Why* does it not have the same effect in all cases? Does it not suggest that the bacillary products of one individual differ from the bacillary products of another individual to the extent that a vaccine from the one cannot represent the symptom complex of all cases in its therapeutic value?

Again, does it not show why a drug is capable of curing diseased conditions in individual cases where the syndrome of symptoms closely resembles the toxic effects of the drug used, and why it fails when that similarity does not exist between the symptoms of the individual and the symptoms produced by the drug in toxic doses?

Tuberculin being a poison and capable of producing toxic effects in the human economy, varying in their toxic symptoms according to the source from which they are obtained, the individual *something* cannot be the same in all cases. Consequently, its curative value must depend on the similarity of symptoms of the patient to the symptoms produced by the tuberculin used. With the autogenous vaccine there can be no variation in the therapeutic effects, as it represents the product of each individual and must cover the totality of symptoms produced by its own poison. If this be true of an autogenous vaccine, does it not suggest that a law of nature is playing an important rôle in the choice of a remedy for all diseased conditions?

Another factor in the use of tuberculin which has caused much discussion has been the question of dosage. In the history of medicine we have abundant evidence as to the effects of massive doses in the treatment of disease. The principle involved in regard to dosage has been, it would seem, to give as much of the drug as the body could tolerate in the process of cure, instead of determining how little was necessary to cure. While this principle has been modified in recent years, we are still cognizant of its evil influence, and especially so is this true in the dose of tuberculin in the treatment of tuberculosis.

With the introduction of the *x*-ray as a therapeutic agent the same principle of dosage has been observed by those enthusiastic students in the *x*-ray realm, to the extent that massive doses have been given, producing in many cases a toxemia with such a rapid breaking down of tissue that the patient has succumbed under its toxic influence.

My investigation in the use of the *x*-ray in tuberculosis has been not to determine how much the body would tolerate in the process of cure, but *how little was necessary to that end.* At the same time to determine the dosage which would be sufficient in all tuberculous conditions, whether in adenitis, in latent infection in the lungs, or in an active degenerative process with intense toxemia.

The greatest problem in this experiment was the question of dosage in the active process; a relatively large dose would materially increase the toxemia present in active processes, through the breaking down of large quantities of bacillary proteins, reducing the resisting power of the patient so necessary to the cure. Reasoning from the fact that the remedial power did not depend on the death of the bacilli *en masse*, but on the vaccine produced by the *x*-ray, I decided to begin with the smallest dose that might be considered capable of producing an autogenous vaccine of sufficient power in overcoming the enemy, at the same time manufacturing interstitially that vaccine in sufficient quantities and strength to keep up a certain daily bombardment.

In 1915, through the generosity of a patient, $10,000 was given for the establishment of a clinic at Flower Hospital in order that experiments on a larger scale might be carried out in the treatment of tuberculosis. For this purpose a complete outfit, made by the Wappler Co., was installed, consisting of a 7½-kw. high-tension transformer (Bellevue model) with a separate switchboard in a lead-lined cabinet for protection to the operator. A Universal stereoscopic and fluoroscopic table. Treatment tube-stand with Coolidge tube and tube cover. Radiographic stand and plate holder. Wheatstone stereoscope. High-frequency machines for autocondensation.

Up to this time the gas tube had been used for all purposes, and while its use resulted in many cures, the dosage was never uniform, owing to the uncertainty in the vacuum, which was ever changing, and consequently unreliable for general use. By the use of the Coolidge tube, complete control for all requirements in a scientific study became possible, particularly so in regard to dosage, which had been, up to this time, a stumbling block in *x*-ray therapy.

In the experiments which followed, a dose sufficient for any or all tuberculous manifestations has been obtained whether in active or quiescent states, at the same time free from danger to the patient, though extended over long periods with daily applications. The combination used for dosage follows: Spark gap 8½ inches. Current 4½ milliamperes passing through the tube. Skin-focus distance, eight inches. Filtration, four millimeters of aluminum. Time of exposure, two minutes. Treatments have been given through the clothing, which acts as a slight additional filter.

Where both lungs are involved, the area of the chest is divided into four parts for treatment; two anterior and two posterior—exposures being made consecutively over the four parts; raying of one part each day, beginning on the right anterior; next day, on the left anterior; third day, right posterior; fourth day, left posterior, repeating in same order. Where one lung is involved, four divisions still being made; upper and lower anterior and upper and lower posterior.

In case of the entire involvement of both lungs, the surface of the chest is divided into eight parts. Exposure being made over any one part once in eight days, while in the four divisions an exposure is made over each part once in four days. The importance of these divisions of the chest-surface is

to cover frequently all parts of the lungs involved, thereby keeping up a continuous inhibitory action.

With this technique I have never produced a dermatitis, even when treatment has been extended over a period of one year, although in sensitive skins a brown discoloration has been observed.

Considerations in addition to the use of the *x*-ray in the care and treatment of these cases may be mentioned. Electricity, air, rest and food.

The influence of high-frequency I consider very important. It is well known that in anemia, which invariably accompanies tuberculous dyscrasia, lies one of the greatest obstacles to its cure, and the influence of high-frequency autocondensation in anemia is as near a specific as we can hope for. Its value in increasing metabolism is also well known, and this combined with red blood so increases the resistance of the body that electricity becomes a valuable aid in the cure, second only to the *x*-ray itself.

Air. The influence of a dry climate and fresh air in high altitudes has so long been considered of such great value in the treatment of tuberculosis that to argue counter to this opinion might be considered by some almost a sacrilige; but my experience in the treatment of tuberculosis has been without this aid.

Of course, no one could object to pure air at any time in any condition; but as a valuable aid, outside that which is possible in every home, it does not materially influence the cure. I have not treated any cases where any change in the usual mode of living has been made. I consider the home comforts of a patient suffering from tuberculosis, no matter how humble that home may be, surrounded by family and friends, of more value than any benefit from a better atmosphere, minus the comfort of home and friends.

Still another consideration in the treatment of these cases at home, and which is, in my estimation, far reaching in its possibilities, not only to the home but to the State as well, is the fact that, among the poor, often the bread-winner of the family is the victim, and unless the patient be suffering from active disease with fever, tachycardia, and prostration, the treatment may be given without his giving up any responsibility on which his family is dependent.

And if patients can be cured in a climate in which they have contracted the disease, there is no reason why they should not remain cured. Patients who have apparently been benefited by living in mountain air are often compelled to remain there for the rest of their lives.

The value of rest during the course of treatment is unquestioned. No one suffering from an intense toxemia, whether typhoid, pneumonic, or tuberculous, can be better off out of bed than in bed, yet, in the cases I have reported several were suffering from a high temperature and rapid pulse. While this does not prove an advantage to the patient, it would rather seem to argue that the treatment was sufficient to overcome the ill effects of such care in many cases. I am sure that if in the cases reported those who were treated under such adverse circumstances could have had the advantage of hospital care, much more might have been accomplished in less time.

The question of food has not been considered of any great importance, other than the best the paitent can afford. Some years ago I was much impressed by the value of concentrated food in large quantities; but I am quite sure now that little has been accomplished by forced feeding. I have seen just as good results among the poor clinic patients as among those who have had every advantage that money could give.

Some Conclusions.—1. Control of tuberculosis is possible in one generation.

2. The Roentgen ray is curative in all stages of the disease.

3. One hundred per cent. of incipient cases are curable with a few months' treatment.

4. A large percentage of third stage cases with cavitation is curable.

5. Quarantine, education of the public against exposure to infection, or State control, cannot materially lessen its dangers.

6. Prophylaxis can be secured by early *x*-ray treatment in the child.

7. All children showing infection, whether in the tonsils, adenoids, cervical, bronchial, mesenteric, or any part of the lymphatic system, as well as in all other tissues, should be placed immediately under the influence of the *x*-ray, thereby arresting the incipient condition and producing immunity for the future.

8. Patients can be treated at home, while living among family and friends.

9. Hospital care is necessary only in cases of great activity and intense toxemia.

10. Ambulant cases can continue in their work while undergoing treatment.

971 Madison Avenue.

CANCER OF THE THYROID GLAND.*

By D. C. BALFOUR, M.D.,

ROCHESTER, MINN.

It is, I believe, the common opinion of clinicians and surgeons that cancer of the thyroid, at least if it has progressed to a stage in which the clinical diagnosis is certain, is incurable. When early malignancy is discovered during the course of operation this pessimistic attitude is not mitigated even by a radical extirpation of the entire gland. Whether such an attitude is justified by the results obtained in the routine employment of the most advanced clinical, pathologic, and surgical methods, is open to some doubt; it is my purpose in this investigation to determine the facts.

The frequency of cancer of the thyroid, as compared with benign enlargement of the thyroid, can only be estimated, since an unknown and probably a relatively small percentage of the so-called "simple" goiter group of patients seek medical or surgical advice. Of 6,359 cases of goiter, exclusive of the exophthalmic group, seen in the Mayo Clinic during the six years from January, 1910, to January, 1916,† we have classified 103 cases as cancer, a percentage of 1.6. The cancer incidence, based on all patients with goiters (14,456) coming to the clinic from January 1, 1910, to August 1, 1918, is 1.19 per cent. The age incidence in the 103 cases is:

*Presented for publication August 21, 1918.

†This period was chosen in order to give a fair indication of results of operation, and to furnish a basis for prognostication as to ultimate results.

8 cases (7.9 per cent.) between 20 and 30
10 cases (9.6 per cent.) between 30 and 40
30 cases (29.1 per cent.) between 40 and 50
30 cases (29 1 per cent.) between 50 and 60
25 cases (23.3 per cent.) more than 60

Eighty-one and five-tenths per cent. of the 103 patients were more than 40 years. Sixty-eight (65 per cent.) of the patients were females, 35 (35 per cent.) were males.

In reviewing this series from the standpoint of etiology the most impressive fact is that in almost every cancer of the thyroid we have seen in the clinic there has been a history of a long pre-existing goiter. In the very few instances in which we have been unable to obtain such a history, it is quite probable that small adenomas existed within the gland, the presence of which were not known to the patient. In our own experience we have not met with a single instance of cancer of the thyroid which gave unmistakable evidence of having developed within a normal gland. This fact parallels the low primary cancer incidence in other ductless glands—the thymus, pituitary, adrenal, the spleen, etc. The significance of this point, that is, the marked difference in tendency toward malignant degeneration possessed by the normal thyroid and the thyroid in which benign tumors (cysts and adenomas) have developed is, that such tumors can be justly considered as points of chronic irritation in an otherwise normal organ.

Langhans stated that cancer of the thyroid originates from unutilized embryonic tissue, and that such tissue remains quiescent until the necessary factor of irritation is introduced, which may be and usually is adenomatous. A further factor of interest in the agency of irritation is that of external trauma. Although patients with small goiters frequently erroneously attribute various sensations in the neck to a direct blow, we have not seen any evidence that malignant change has been occasioned by injury to the gland. However, there have been observed in the clinic seven cases in which malignancy occurred in an enlarged thyroid that had previously been "treated" by injections of various irritants and by the application of "absorbents." Such cases are even more convincing examples of the fact that chronic irritation is the chief factor in inducing malignant changes and should be the final argument against useless and dangerous methods of treatment. As pointed out by Plummer, the disease has never, in our experience, developed in a distinctively and purely hyperplastic gland.

The clinical diagnosis of cancer of the thyroid is relatively simple when the process is advanced, but it is impossible when the malignancy is in the early stage. The diagnosis of malignancy, before it can be recognized as such by palpation, can only be based on the rate of growth. Malignancy must always be considered when a history is obtained of rapid growth of a goiter that has been more or less stationary in size. In well-developed cases the board-like resistance and the fixity of the gland are sufficient to justify a diagnosis of malignancy, if the history and Wassermann test have excluded the rarer conditions of hemorrhage, acute thyroiditis, and syphilis. Moreover, when the disease has become recognizable by palpation, symptoms and signs of pressure, either tracheal or esophageal, are usually present. Rarely hoarseness and dysphagia may be early in evidence, and, in the absence of other symptoms, may be suggestive.

The relative frequency of thyroid malignancy in which there is an absence of signs or subjective symptoms, is well shown in this series of cases. In only 18 per cent. could a positive clinical diagnosis of cancer be made. In 36 per cent. malignancy was considered as a possibility in the preoperative diagnosis, while in 46 per cent. the condition was not even suspected until it was discovered during the course of operation or later by pathologic examination. It should be stated that the latter figure (46 per cent.), although it represents the number of cases of cancer of the thyroid in which no note was made of such a possibility, could be lowered if in the large group of hard, firm adenomas which we see in the clinic, the possibility of malignancy should be regularly noted. In doing this, however, the total percentage of accuracy in diagnosis would be considerably lowered, because of the small percentage of such adenomas that are malignant, and as surgical treatment is clearly advisable in the entire group, the discussion as to the question of malignant change is not only merely of academic interest but dangerous in its tendency to delay.

It is, of course, true that not infrequently malignancy has been clinically suspected, although no evidence of it was found at operation. This is chiefly explained (1) by the fact that certain changes simulating malignant degeneration occasionally take place in an enlarged thyroid (the most confusing cases are low-lying adenomas in which there has been a considerable deposition of lime salts), and (2) because the clinician, being aware that this large percentage (46) of malignant cases found at operation shows insufficient evidence to support even a provisional diagnosis of malignancy, accepts the chance of an error in the hope of exhibiting diagnostic acumen.

These figures are most eloquent testimony of the difficulty of diagnosis of early carcinoma of the thyroid; in no other region of the body is beginning malignancy so well concealed. The explanation of this fact is found in the close analogy between benign nodules and malignant masses, as in both there is a marked tendency for the masses to remain covered by healthy thyroid tissue and not to reach the thyroid capsule until each has attained considerable size. This similarity should be stressed for it means that the signs of malignancy are not noticeable until the process has been in existence for some time, and for this reason a strong argument is added for early operative interference in cases of nodular goiter. It means, too, that only by such interference will the cancer incidence in the thyroid be lowered. Just as in other conditions that are either definitely precancerous or provocative of cancer, such as chronic gastric ulcer, gallstones, and cervical erosions, it is criminal to agree to delay operation in the belief that malignant changes can be recognized in time, so in cases of nodular goiters, waiting for evidences of malignancy is even more inexcusable and is fatal to the best interests of the patient.

The difficulties of diagnosis, moreover, are not wholly concerned with the clinical manifestations of the disease. Carcinoma of the thyroid gland may be of such a broken down character, particularly when the malignancy has developed within a cyst, that it is occasionally difficult, either at operation or by pathologic examination, to differentiate benign and malignant necrosis.*

An atypical microscopic picture is responsible for the fact that in several instances a surgical diagnosis of malignant goiter has been made at operation without a confirmation by the pathologist. It is of importance to note that in some of these cases, although the surgical opinion remained unsupported after repeated pathologic examinations, the later developments proved that the surgical diagnosis was correct. It is advisable, therefore, in such cases, to recognize the relative value of the surgical record, and of the pathologic report. A discrepancy between the surgical record and the pathologic report is most likely to occur in those cases in which the malignancy is of very low grade activity, and in which the pathologic picture is that of simple goiter.

Diagnostic difficulties at operation are also found in those cases in which muscles and thyroid capsule are adherent, due to the inflammatory changes that have followed injections, or other local treatment. The diagnosis, however, in this group can usually be made at the operating table from the fact that if the condition is benign the indications of malignancy become less with further exposure of the gland, while in cancer the reverse is true.

Errors in diagnosis have also occurred because of the fact that a malignant process may develop in close relationship to but quite independent of an enlarged thyroid. The following case will illustrate: The patient, Mrs. J. O. A. (Case 82318), had an adenoma the size of a large grape fruit in the right lobe. Following the enucleation of this adenoma, I found a mass the size of a small lemon crowded up in the right submaxillary triangle. It was hard and adherent to the surrounding structures and at first was thought to be a malignant superior pole of the right lobe. Further investigation, however, proved it to be a carotid body tumor, which necessitated an extensive dissection for its removal.

Rarely have the clinician, the surgeon, and the pathologist all erred in pronouncing a given case to be malignancy of the thyroid when the future course of the condition proved the error in the diagnosis. This occurred, however, in one case in the present series. The patient exhibited a hard infiltration of the entire gland with a history of rapid enlargement and marked tracheal pressure. A clinical diagnosis of probable carcinoma was made and at operation the condition was thought to be malignant and the tumor irremovable. A section for microscopic examination was pronounced carcinoma. The patient seven years later is in good health with no marked enlargement of the gland. In all probability this was a case of thyroiditis of the "woody" type described by Riedel.* The thyroid gland being unique in its power to develop hyperplasia of its cellular elements, in certain types of infections, occasionally simulates very closely a malignant degeneration.

In considering the indications for operation and the surgical problems to be met in the operative treatment of malignant thyroid tumors, it may first be stated that when the clinical diagnosis is positive, surgical interference should be advocated only under exceptional circumstances. In our own experience, at least, infiltrating, diffuse, advanced cancer of the thyroid, when the capsule has been perforated and muscles and glands involved, has never been cured even by the most radical methods, and such methods are attended by a prohibitive risk. Under such conditions, therefore, the only purpose of surgery would be the relief by tracheotomy of tracheal pressure with actual or impending suffocation, and even this procedure may be one of considerable technical difficulty, great risk, and dubious results. As a rule, therefore, it is much better to advise the use of radium, roentgen ray exposures, and whatever other palliative measures there are available.

Even when the malignant process is less extensive and the anterior and lateral relationships of the gland make it appear possible and reasonably safe to remove the entire gland, it is important to remember that there is a liability to encroachment of the disease on the trachea, the esophagus, or both. This complication may vary between actual invasion of these structures and firm attachment to them without involvement. In the first complication the possibility of obtaining a cure is rendered very unlikely, although we have had one case in which the lateral wall of both the trachea and the esophagus was excised with the thyroid; the patient is alive and well seven years afterwards. In the second complication, the malignant mass may be crowded between the trachea and the esophagus, so that in the traction necessary to expose this portion of the tumor the esophagus may be dragged out of its bed and injured before being recognized. An esophageal fistula is, therefore, one of the possible secondary complications, and has occurred after the removal of a malignant thyroid.

The more frequent and more urgent surgical problem concerns the trachea. When there is marked tracheal obstruction prior to operation in a malignant thyroid, the tracheal rings, even if not invaded by the disease, are oftentimes so softened that tracheal collapse may occur at a most inopportune moment and with comparatively little provocation. As C. H. Mayo early pointed out, the trachea in malignant goiter is more apt to flatten itself in an anteroposterior direction than to develop the scabbard trachea which is seen in benign and bilateral enlargements of the gland. Therefore, when there is evidence of tracheal pressure, especially if malignancy is suspected, any measure should be made use of that will minimize the technical difficulties and the risk of operation. Among such measures the most important is local anesthesia.

Since tracheotomy is not an unusual emergency

*Dr. L. B. Wilson, when he left for active service in France in February, was independently preparing a complete study from a pathologic standpoint of the malignant thyroid tumors.

*Riedel: Quoted by Crotti, A., "Thyroid and Thymus," Philadelphia, Lea & Febiger, 1918, 109.

operation in malignancy of the thyroid, the surgeon, who has acquired the ability, by practice in surgery of nontoxic goiter, of quickly isolating the trachea as the first step after the surface of the gland has been exposed, is in an advantageous position when such an emergency arises. In some cases the necessity for tracheotomy may occur while the patient is being prepared for operation; it may occur at any time during the course of the operation, or, more rarely, during the post-operative period, even though the gland has been entirely removed.

Tracheal obstruction, after total or subtotal thyroidectomy, may be owing to one or all of the following causes and conditions: (1) Injury during operation to the nerve supply of the laryngeal muscles; (2) secondary edema of the tracheal mucous membrane; (3) secondary hematomas, and (4) softened tracheal rings. As a measure of safety, following operation for malignant thyroid, it is wise to have in the patient's room the equipment necessary to perform an immediate aseptic tracheotomy.

In this connection it is of interest that the possibility of secondary tracheal obstruction is not restricted to malignant conditions. I have had one such case occurring in a nontoxic goiter. There had been nothing unusual in the operation except that it was necessary to remove a large amount of thyroid tissue, as the enlargement was due to multiple degenerating adenomas, which had extensively involved both lobes. After enucleating the tissue from all the diseased areas of the two lobes by the double resection method, comparatively thin shells of thyroid tissue remained. Further, along with the treatment of the lateral lobes, the removal of a large pyramidal lobe, which had wrapped itself around the upper rings of the trachea, necessitated a rather extensive stripping of the trachea. Nothing occurred during the course of the operation to give warning of the immediate or late complications, but the following day the patient complained of difficulty in breathing, which gradually increased; the breathing became crowing in character, and, thirty hours after the operation it was necessary to do a tracheotomy. It was a surprise to find no visible cause for the obstruction, as the operative field was in perfect condition. The tracheotomy tube was left in place for forty-eight hours, and its removal did not cause any recurrence of the difficulty. The complication in such a case was probably the result of an edema of the mucous membrane brought about by the close dissection of a large surface of the trachea.

Total thyroidectomy must, of course, be followed by the administration of thyroid substance. The recent studies of Plummer, which establish the exact relationship between thyroid activity and metabolism, for the first time have made it possible to determine with absolute accuracy the amount of the active principle of the thyroid necessary to maintain normal metabolism in such cases. Since this is possible, and since Kendall has been able to isolate and synthetically to produce the active principle in thyroxin, any objection to total thyroidectomy in malignancy of the gland on the score of postoperative disturbance in metabolism is practically eliminated.

In those cases in which malignancy has not been suspected, but is discovered at operation within the substance of an adenoma, the question of total extirpation of the gland must be determined at the time. In reviewing the results in such cases it has been interesting to find that total thyroidectomy was rarely performed under such circumstances, and the indications are that radical extirpation is unnecessary.

Before discussing the results of operation in malignant cases, it is well to consider the question of the danger of malignant change taking place after operation for simple goiter. The fact that occasionally patients who have been operated on for a simple goiter have later developed malignancy in the remaining portion of the gland, raises two questions, first, whether malignancy has been overlooked, and second, whether real cancer-prophylactic value is secured in operating in simple goiter.

The first possibility of overlooking a malignant process in the portion of gland remaining cannot be denied. This apparently occurred in one patient in the series, from whom a lobe had been removed, and who returned to the clinic in about six months with malignancy well developed in the opposite lobe. We believe, however, that with the present methods of conducting operations in simple goiter the risk of such malignant development is a negligible factor. In 90 per cent. of operations at the clinic for simple goiter, a double resection which insures a thorough exploration of both lobes for adenomatous masses, both small and large, is done. With such a principle carried out as a routine procedure, the danger of leaving adenomas that might attain further growth, either benign or malignant, is reduced to a minimum. Inasmuch as cancer in the thyroid almost invariably develops from within outward, as pointed out by Kocher, this exploration of the interior of the gland is of the greatest importance in making possible the early detection and removal of cancerous or precancerous adenomas.

The further question as to the assurance which can be given a patient in regard to the danger of malignant change taking place in the thyroid after the operation can be answered by saying that, although such assurance cannot be absolute, it can be practically so. An incontrovertible argument for operation in cases of adenomatous goiter is the fact that cancer is practically not known to have developed in a healthy thyroid gland. Pre-existing disease has always been in evidence, so that adenomatous goiter may be looked on, to a certain extent, as a precancerous condition. It is to be hoped, therefore, that adenomatous goiters in the future, will not be permitted to develop malignant changes, but that surgical assistance will be sought opportunely and, with the correction of the deformity, the catastrophe of malignancy be obviated.

In considering the results, the investigation of which was my primary object in writing this paper, it was found that of the 103 cases of cancer of the thyroid seen in our clinic, 63 patients have come to operation. The remainder, constituting 38 per cent. of the number in which there was a positive preoperative diagnosis of cancer, have been put on x-ray or radium treatment.

Definite information* regarding 42 of the 63 patients was secured. Four of the patients operated on died while under our observation. Twenty of those who survived the operation are now dead, all apparently of the disease. They lived from a few weeks to four and one-half years. Of the remaining 22 patients the information is positive in five instances of extensive recurrence, and a probable early death. In 17, however, there is freedom from any evidence of recurrence, and the patients are in good health. In three of these the operation had been done less than one year, in three between one and two years, in four between two and three years, in one between three and four years, in five between four and five years, and in one more than five years. To recapitulate, 6+ per cent. is the operative mortality; 47.6 per cent. died soon from recurrence; 11 per cent. have recurrence; total 65.6 per cent. deaths or probable early death from the disease.

Thirty-five per cent. show no evidence of recurrence in from one to five years, but this percentage cannot be taken as representing the actual utilmate results because of the short time which has elapsed since some of the patients have been operated on and of the fact that in cancer of the thyroid unusually late recurrences are not rare. Only 14.6 per cent. of patients with diffuse carcinoma are alive without recurrence. Of the cases of carcinoma within an adenoma, without gross or microscopic evidence of malignancy in the gland-tissue outside the wall of the adenoma, 69 per cent. of the patients are alive without recurrence. A study of these results in the series of cases and of the individual cases gives us valuable information as to what can be accomplished in the surgical treatment of cancer of the thyroid:

1. The most important lesson is presented in the fact that in 46 per cent. of the cases of cancer of the thyroid, no clinical manifestations of the disease were in evidence. This group shows by far the highest percentage (about 70) of patients free from recurrence at the present time. In other words, the great majority of apparent cures have occurred in those cases in which the malignant change was an unexpected finding. Total thyroidectomy was rarely performed in this group. In most instances the lobe containing the tumor and the malignant process was removed, but in many the enucleation of an adenoma was the procedure.

2. In any nodular goiter suddenly exhibiting an increased rapidity of growth, immediate surgical treatment should be urged.

3. When clinical evidences of cancer are present the results of surgical treatment are discouraging. Total extirpation of the gland appears to be indicated only when both lobes are grossly involved in the disease, and when past experience warrants surgical interference in the particular case.

4. Recognizable involvement of cervical glands usually means that the time for surgical cure is past. Occasionally, however, just as the unexpected occurs in the treatment of extensive cancer elsewhere, an apparent cure is obtained. In 1913 I removed from a patient (Case 81854) the right lobe of the thyroid containing a malignant adenoma. A mass of glands in the submaxillary region was also proved to be carcinomatous. A week later a block dissection was done. The patient is now alive and well, with no evidence whatever of recurrence. Such cases are, however, notable exceptions to the rule.

5. Gross involvement of trachea or esophagus is almost a certain sign against curability, and yet one may be tempted into an extensive and dangerous operation to remove the diseased tissue because of the knowledge of an unexpected result in the past. A patient (Case 73753) was operated on (by E. S. Judd in 1912) for a malignancy of the left lobe which was found to involve the lateral walls of both trachea and esophagus. The involved areas were both excised, with primary closure, and although bougies were required later to maintain the caliber of the esophagus, the patient is now, six years after operation, in perfect health and has no local disability.

6. The last and most important lesson learned from the standpoint of prophylaxis is the fact that in this series the average number of years of abnormal growth in the thyroid preceding the operation was 11.6. This is proof positive of the advisability of the early removal of well-developed thyroid nodules, and it is a regrettable fact that not infrequently we meet with cases of hopeless thyroid cancers in which a tumor has been present for many years, but the patient had been able to secure the advice of "leave it alone, it will never bother you."

Finally, the treatment of cancer of the thyroid should be that of the treatment of precancerous lesions elsewhere; that is, prompt surgical treatment of the precancerous condition in the thyroid —the adenoma.

*These data were secured during 1917-1918.

SHALL WOMEN STUDY MEDICINE.*

By ANNIE S. DANIEL, M.D.,

NEW YORK.

In an address by Doctor Elizabeth Blackwell on "The Medical Education of Women," delivered Dec. 27, 1855, she said, "I want it clearly borne in mind that the medical practice of women is no new thing, but a necessity of society which must always be supplied."

In an address by Dr. Mary Putnam Jacobi in 1878, quoted by Dr. Cushier in an unpublished history of the College, she called attention to the fact that the study of medicine by Dr. Elizabeth Blackwell had long been preceded by the practice of medicine by women, and it was not until educated women *asked* to study medicine that oppositions arose. The goddesses of Egypt and Greece practised medicine. In the 11th century B. C. there existed in Egypt a College of Physicians who seem to have been of the sacerdotal class and were certainly of both sexes.

Women studied medicine in the school of Hyppocrates 420 B. C. But the Greeks thought to add dignity to the practice of medicine by forbidding the study to slaves and women. Then 300 B. C. a young woman of Athens disguised herself as a

*Read before the Woman's Medical Association of New York City, October 16, 1918.

man, and studied and later practised as a man. (It will be remembered that Doctor Elizabeth Blackwell was urged to study medicine in the same way.) But trouble came when this disguised woman was found treating women patients. She was obliged to disclose her sex and then was prosecuted for violating the law prohibiting slaves and women from the study of medicine. But the wives of the most influential Athenians arose in her defense —and this woman of Athens by her skill brought about the legal opening of the study of medicine to all free born women of the State. Dr. Blackwell by her genius in overcoming obstacles brought about the same results two thousand years later. Apparently women have always practised medicine, but it seems that there have been periods in which they have been admitted to the medical schools and then others in which they were refused admission.

It is claimed for the schools of Italy that they have never been closed to women. The same claim has been made for France, but in 1866 a woman applied to the Faculty of Montpelier and was refused; later she applied in Paris and was allowed to study on condition that she would practise in Algeria. In 1871 Doctor Mary Putnam Jacobi graduated from the Paris School. Always both men and women have practised medicine and at the same time have been teachers of religion. Even to this day medicine has never been entirely separated from religion. The first medical work published in America in 1677, entitled a "Brief Guide in the Treatment of Smallpox and Measles," was written by a clergyman. In March, 1638, under the heading "A Female Practitioner Restrained," we read that Jane Hawkins, the wife of Richard Hawkins, had liberty until the third month called May, when the magistrates threatened to dispose of her if she did not depart before, and in the meantime she was not to meddle in surgery or physick, drinks, plasters, or oils, nor to question matters of religion except with the Elders for satisfaction. Just what Jane had done to bring upon her this punishment I cannot find out—probably after the manner of her sex she had asked some questions which no man could answer. Jane Hawkins lived in Massachusetts, where the men have always had trouble in restraining the desires of their women for knowledge. Until shortly before the Revolution there was no distinction between the educated and uneducated physicians. The first medical school in America was founded in Philadelphia in 1765. The first medical law in this State in 1760 was made to regulate the practice of Physic and Surgery in the City of New York. No provision was made for the study of medicine, no one could practise medicine unless approved by one of His Majesty's Judges of the Supreme Court, the Attorney General, and the Mayor; they could if they saw fit call other persons to their help, and a certificate could be given the candidate.

In 1650 an ancestress of our Doctor MacNutt was called to practise medicine on the Island of Nantucket. She was especially skilled in the treatment of fevers.

The first autopsy was made in New York in 1750. Then the Revolution came. Doctor Putnam Jacobi said, speaking of the men at this time, their public services in the military hospitals, though apparently not very useful to the sick, yet served to bring the profession for the first time out of obscurity. Probably the women also wished to be brought out of obscurity and had asked for rights which had called forth these remarks from a Boston physician —"It was one of the first and happiest fruits of improved medical education that females were excluded from practice, and this has only been effected by the united and persevering efforts of some of the most distinguished individuals in the profession." They were excluded not only from the practice of general medicine but from that of obstetrics. Then followed violent discussions opposing man midwifery, and curiously the same objections were made against men practising obstetrics as were later brought forward against the admission of women in medicine.

In 1792 the first law in this State was made concerning the study of medicine before coming before the Judge of the Supreme Court. The applicant must have studied with a physician two years if the preceptor had studied in Europe, or three years if his education had been in America. This law directed the judges to call to their assistance physicians. The men had taken a step forward, quiet reigned, and women practised medicine. But the women generally were restless; they wanted to study about everything, and opposition arose. Boys had studied in schools and colleges since 1636; girls in schools since 1771. Two hundred years elapsed between the founding of the first college for boys and the first college for girls. Then in 1845, after teaching school, Elizabeth Blackwell felt that she needed an "absorbing occupation." She states that she was rather repelled by the thought of the practice of medicine. She had been told that there was no way for a woman to study medicine, but again she writes, "This idea of winning a doctor's degree gradually assumed the aspect of a great moral struggle and the moral fight possessed immense attractions for me." The story of this fight is familiar, and the final victory—January 23, 1849, when she received her doctor's degree. In her writings, Doctor Blackwell lays great stress on the necessity of the practical study of medicine in hospitals. Her first vacation at college she decided to study at Blockly Hospital in Philadelphia. She was told that the institution was dominated by party feeling—one of the directors told her that he was a Whig and should he bring forward the application it would be much opposed by the other two parties, the Democrats and the native Americans—so she did what she calls "lobbying." The result was the vote was unanimous for her admission; the first time that it had ever been unanimous. She spent a very profitable summer of study.

Harriet Hunt, who had been practising medicine at Boston for several years *without opposition*, applied to Harvard Medical School for admission to study medicine in the fall of 1847. She was promptly refused. In 1850 she again applied. The medical faculty took it up and voted five for and two against admitting her. A week later, the President and Fellows voted no objections to admitting female students, but expressed no opinion as to the claims of such student to a medical degree. At the beginning of the Session, two colored men and then a third "black" had appeared

among the students, then the announcement of the woman. The indignation of the student body was great. They met and passed resolutions against "the amalgamation of sexes and races." They threatened to go to Yale in a body. No record is made of the fate of the "blacks," but the woman was advised by the faculty to withdraw, which she did. Dr. Putnam Jacobi writes, "The storm subsided, and the majesty of Harvard, already endangered by the presence of the negro, was saved from the further peril of the woman." So, unable to study medicine, Miss Hunt went back and practised medicine for more than twenty-five years.

In strong contrast to this attitude of the Harvard students was the behavior of the farmers' sons at the Geneva College. On Oct. 20, 1847, when they met, they passed resolutions that "one of the radical principles of a republican government is the universal education of both sexes, and that in every branch of scientific education the door should be open to all," and they pledged themselves that no conduct of theirs would ever make Elizabeth Blackwell regret that she had become a member of their class—and they kept their promise. Other women were asking to study medicine, and, being refused, they were told to get their own school. So the Boston Female Medical School was opened Nov. 1, 1848, with twelve students and two professors. It had rather a stormy existence, and in 1874 became merged into the Boston University. Then followed the Women's Medical College of Pennsylvania—which seems to have originated with Doctor Fussell, a poor schoolmaster, who had been educated by an elder sister, and he thought that such as she ought to have a chance of studying medicine if they desired. Women applied at the University of Michigan. The Medical Department had been opened in 1851; in 1870 a committee was appointed to study the question of coeducation. Mighty reasons for and against were brought forward, and this committee suggested separate schools with a female medical college at either Ann Arbor or Detroit. Women were admitted in 1871. In New York, Dr. Blackwell, after trying to open the colleges by collecting money and offering to pay for students in existing colleges, was told to get her own colleges.

The two prominent features of our college, the Woman's Medical College of the N. Y. Infirmary, was first, the establishment of the first Chair of Hygiene in this country. Men had long been talking of the necessity of studying the prevention of disease, and in an address before the State Medical Society and the members of the legislature in 1849 called "The Plea of Humanity in Behalf of Medical Education," Dr. Alex. Stevens spoke of the little knowledge among medical men in regard to hygiene, and suggested that it be taught in the medical schools. This lack of knowledge was deplored, but nothing was done until the Blackwells made the study obligatory. The second distinguishing feature of this woman's college was its board of examiners. Various laws had been made by the State (the first State law was 1797) to regulate the study and practice of medicine. In 1806 the law to incorporate medical societies for the purpose of regulating the practice of medicine had been made, and various penalties had been more or less enforced until 1843, when the laws relating to penalty for practising without a license were repealed. Much discussion had also arisen as to the wisdom of allowing the college to grant with its diploma the right to practise medicine. The result of this was the springing up of colleges granting diplomas with little or no education. The women of Doctor Blackwell's college were required to pass their own faculty and then the Board of Examiners before the diplomas were granted, and this the college continued to do until the State Board of Examiners was establishd by law. From the first also residence in the infirmary and attendances upon a certain number of obstetrical cases were obligatory. In an address before the Medical Society of the State of New York in 1837, suggestion was made that every one before he aspired to the degree of M.D. should have had practical experience in some hospital for at least six months, and it was urged that in New York this arrangement be made at once. It remained for the Blackwells to carry this arrangement out.

Now the needs of a world war have opened practically all the college doors to women. This has ended one phase of the struggle of women to study medicine. Shortly after the Revolution, medical men formed societies as a means of mutual education and to control first the practice of medicine and later the study of medicine. For admission into these societies women applied, but met with opposition, long and bitter. In 1859 application was made to the Philadelphia County Medical Society, with the result that a resolution was passed declaring that any member who consulted with women should forfeit his membership. The resolution was taken to the State Medical Society, and the only county refusing to endorse it was Montgomery County, which resolved that "females should receive the same treatment as males." The contest continued at every State meeting until 1870, when Montgomery County elected Dr. Anna Lukens to membership. Equally long and bitter was the war waged in Massachusetts, where not to be a member of the County Society meant that the woman was classed among irregular practitioners. For twenty-five years they were refused; then on October 9, 1879, an editorial appeared in the *Boston Medical and Surgical Journal* stating "We regret to be obliged to announce that at a meeting of the Counsilors, October 1, it was voted to admit women to the Massachusetts Medical Society." Soon after that Dr. Emma Call passed a satisfactory examination and was admitted to the society. What was called the "female physicians question" was brought before the American Medical Association in 1871, and all the old familiar excuses for refusing admission to women were repeated. Dr. Johnson of Missouri said, "Let women have their own associations; this body will stultify itself by the admission of women." The question at one time was debated on the ground that once a month women's judgment could not be depended upon—this from a Boston doctor. A California man came to the rescue of the women by saying that "It is a fact that a large majority of male practitioners fluctuate in their judgment—not once a month with the moon, but every day with the movement of the sun," and then stated that one-half of the

medical men were to a greater or lesser extent under the influence of alcohol at some period of the twenty-four hours. These discussions continued until 1876, when Illinois sent as a delegate Doctor Sarah H. Stevenson, who was admitted without debate. The first States to admit women were Kansas and Iowa in 1872, then New York in 1875.

In 1888 there existed a national Woman Physicians' Association, of which Doctor Mary A. Allen was president. Dr. Putnam Jacobi says that the first admittances of women to any medical society was in 1869, when Doctors Elizabeth and Emily Blackwell were admitted to the Medical Library and Journal Association—distinctly a society for education. With the opening to them of the medical societies women secured another opportunity to study medicine.

After coming to New York to begin the practice of medicine, Doctor Elizabeth Blackwell applied at the existing dispensaries for the opportunity of increasing medical knowledge which such institutions afford. She was told to get her own dispensary, which she did in 1853, and immediately made it a teaching center for young women, either undergraduates or those with diplomas. Then wishing to study medicine further, she applied for admission to study in hospitals, only to be told again "Get your own hospital." Then in 1857 was begun the "cautious experiment" of opening a hospital, one of the objects of which was the opportunity for women to study medicine at the bedside of the sick. The study of medicine by women will never be complete until every dispensary and every hospital is open on equal terms to every physician without regard to sex. What have we in New York? The first general hospital to appoint a woman interne was Mount Sinai in 1874, another woman was interne at the same hospital, which is now closed to women. Internes have been received in the Babies' Hospital, Bellevue, and the Lying-In Hospital. This much can the recent graduate find to study medicine. A woman assistant attending physician is at the Woman's Hospital. Dr. Mary Putnam Jacobi was attending physician at St. Mark's Hospital, but when she became too ill to perform the work they refused to appoint another woman. Doctors MacNutt and Peckham Murray have been attending physicians at the Post Graduate. Dr. Putnam Jacobi was the first Professor of Pediatrics at the Post Graduate Hospital Medical School. Women occupy certain specialties as anestheticists and radiographers, but the hospitals are not yet fully open to women. A woman may, as stated, enter and do good work—and then the door closes upon other women. They are not open any more than the Geneva College was open to women when it admitted Elizabeth Blackwell. The only hospital in this city which was really open to women is closed. That women may study medicine it is absolutely imperative that the infirmary doors be reopened wide that any woman may take her patient there and treat and study disease. Last spring Doctor Lambert, in his address, said that women entering Columbia would need the infirmary, and we were told to get our own hospital. Upon the medical women of New York depends the answer to my question—Shall women study medicine?

26 Gramercy Park.

THE ETIOLOGY OF FIFTY CASES OF DRUG ADDICTIONS.

By CARL SCHEFFEL, Ph.B., M.D.,
BOSTON, MASS.

The following is a study of the etiological factors involved in the causation of the drug habit in a series of fifty patients voluntarily presenting themselves for treatment for the purpose of being freed from the clutches of the drug to which they became addicted.

The offending drugs include bromides, chloral, cocaine, heroine, opium, and morphine; the latter named being the habit-forming drug in forty-one of the fifty addictions. The statements as to the causes of their addictions were obtained as a part of the patient's medical history, and were verified whenever possible by the physician referring them for treatment.

Etiology.	Drug.	Number.
Asthma	Morphine	2
Biliary Calculi	Morphine	3
Chronic Gastritis	Morphine	1
Chronic Dysentery	Morphine	1
Chronic Dysentery	Opium	1
Chronic Headaches	Morphine	4
Chronic Headaches	Heroine	1
Chronic Headaches	Bromides and Chloral	1
Chronic Vomiting	Morphine	1
Chronic Appendicitis	Morphine	1
Chronic Rheumatism	Morphine	1
Duodenal Ulcer	Morphine	1
Dysmenorrhea	Morphine	3
Insomnia	Morphine	5
Insomnia	Chloral	1
Luetic Stomach	Morphine	1
Brachial Neuritis	Morphine	1
Neuroses of Stomach	Morphine	1
Overwork	Bromides	1
Post Operative Adhesions	Morphine	3
Renal Calculi	Morphine	1
Sciatica (Chronic)	Morphine	1
Social	Morphine	3
Social	Cocaine	1
Treatment for Alcoholism	Morphine	5
Treatment for Alcoholism	Chloral	1
Tri-facial Neuralgia	Morphine	1
Tri-facial Neuralgia	Heroine	1
Traumatic Neurosis	Morphine	1
Unknown	Opium	1
Number of causes		23
Varieties of drug		6
Number of patients		50

From a careful study of the above table it becomes at once apparent that insomnia and various types of recurrent headache rank foremost in the list of etiological factors. There seems to be, in the light of our modern therapeutic knowledge, no good reason why morphine or any other habit-forming drug should be resorted to in the treatment of insomnia; and yet every one of the six cases cited were given the drug to which they became addicted, by physicians for the relief of insomnia before they finally resorted to its use of their own initiative.

Next to insomnia as an unjust cause for which morphine is very frequently administered is the treatment of alcoholism. To be sure, jabbing morphine into a patient recovering from the effects of "the night before" may be the easiest way for the physician to relieve his patient; but when cognizance is taken of the fact that this procedure is apt to be repeated over and over again, and that it directly caused 8 per cent. of all the drug addicts in the table above, it becomes apparent what a really dangerous method it may become to the patient. Creating a morphinist out of an alcoholic is simply pulling him out of the frying-pan and throwing him into the fire.

Many physicians, and most laymen, have the impression that most drug addicts are a type of social outcasts who became addicted to the use of narcotics of their own accord. Nothing is further from the truth than such or similar impressions. From the table—which presents a good average of the etiology of drug addictions—it will be seen that about 92 per cent. of all addicts were caused either through the inability of the profession to relieve or cure difficult chronic conditions; or by the careless and promiscuous administration by physicians of dangerous habit-forming drugs over long periods of time, and many times in conditions where habit-forming drugs were not absolutely indicated.

Out of the fifty patients only 8 per cent. resorted to the use of habit-forming drugs entirely of their own accord, not due to some form of illness for which they were first given some form of dope. Two of these addicts were males, and two were females; all were below thirty years of age, and all were of a high intellectual type. One of the males drifted into bad company and commenced by smoking opium in the slums, later shifting to morphine for a "stronger sensation." The other male became addicted to the use of cocaine as the result of frequenting a house of prostitution whose inmates all used it. Of the females, one was a prostitute and the other a woman who used to attend regular "dope parties," at which a number of girls and women would regularly meet to "shoot dope and sniff snow." Of these fifty patients, eleven, or 22 per cent., were physicians.

What lessons may we learn from the foregoing figures? In the first place, and it cannot be too strongly emphasized, physicians are making more addicts to habit-forming drugs than the profession would like to admit. Most hypnotics and practically all analgesics that are given internally may be habit-forming under certain conditions. They should be used with extreme caution, and not promiscuously as is now only too often the case.

In insomnia and allied conditions it is not justifiable to give veronal, trional, bromides, chloral, or the opium derivatives over long periods of time, even though so doing may be easiest for the physician and for the time being most pleasing to the patient. Past experience has repeatedly demonstrated that insomnia, nervousness, and allied conditions may be efficiently combated with other therapeutic agents than the dangerous administration of habit-forming drugs.

Where pain is the dominating factor, its cause should, if possible, be removed. As may be seen from the table, conditions producing various degrees of pain are by far the greatest etiological factors in producing drug addictions; and for the same reason morphine is the most frequent drug resorted to. Not always is it possible to subdue pain by ordinary means, and, in many acute painful conditions a hypodermic of morphine is the only appropriate remedy. It is in the chronic conditions associated with more or less continuous or recurrent pain that extreme caution is called for in the administration of habit-forming drugs. It is nothing unusual to see some chronic condition treated with morphine until the habit has been established, which might have been remedied by surgical or other means. Various forms of colic and dysmenorrhea are often the cause of drug addiction, only to be cured after the removal of renal or biliary calculi or proper gynecological treatment. Why not remove the cause first instead of making the sufferers slaves to drugs only to require surgical interference eventually?

It is true, all physicians cannot be expected to be expert diagnosticians; neither are pain-producing conditions always relieved by means other than the use of morphine; but to those dealing with drug addicts it is apparent that there is a tendency on the part of too many physicians to administer analgesics or sedatives promiscuously rather than to take the pains to make exhaustive diagnostic investigations or to utilize time-consuming therapeutic measures.

There is no denying the fact that almost all hypnotics and analgesics, if used any length of time, will produce in most patients a desire for more, provided they temporarily relieve them. If one physician refuses to repeat the prescription, the other very likely will. What usually follows is that if the patient is able to learn what he is taking it will be only a matter of time before he will obtain and use the drug himself—and so another drug addict is created!

The various hypnotics and analgesics are not safe in the hands of the laity, and when our table shows 22 per cent. of physicians to be the victims, it may be safely stated that such drugs are not safe for self-administration by patients of any class.

When suffering humanity have access to something that will even temporarily relieve them of their pains and discomforts the temptation to use it is too great to be withstood by the average individual. The comforts and sensations temporarily derived from them inhibit the powers of reasoning and judgment, even of those who have been taught the dangers of their continuous administration; they give no thought to the future that is sure to come, when the drug that once gave them temporary relief will have become their master and enslaved them in its clutches. If this effect is so on physicians themselves, what may we expect of the laity? Before resorting to repeated doses of habit-forming drugs in any given condition, physicians should make doubly certain that nothing else will be effective—and always as a last resort. Greater caution and conservation in the use of habit-forming drugs must be practised by the medical profession if we wish to avoid being the creators of a large percentage of all drug addicts.

1127 Commonwealth Avenue.

Exotic Drugs of the War.—Guérin writes that ergot of rye, once obtained from Russia, must now be had from Spain. The cantharides which was once shipped from Libau is now imported from China. Pyrethrum, once a Montenegrin staple, must now be obtained from Japan. Instead of Hungarian, domestic leeches are used. Tarry products which came from Finland have now been replaced. Numerous drugs once received directly from remote countries must now be bought of the English.—*Revue Scientifique.*

A NEW METHOD OF PERCUSSION.

By ALBERT ABRAMS, A.M., M.D., LL.D.,

SAN FRANCISCO, CAL.

In percussion, despite its antiquity and supreme clinical importance, it is difficult to eliminate the personal equation and the prejudiced preconception of perceiving what is expected to be perceived. In dwelling on the deficiencies of this art the writer does so not as a rebuke to the herculean efforts made by traditional investigators, but to arraign our complacency which accepts things as they are and to view as a sacrilegist any one who questions establish methods. Five physicians of local prominence in San Francisco were in attendance on a patient. All concurred in the diagnosis of appendicitis and the necessity of an immediate operation. "Gentlemen," said the patient, "I do not doubt the accuracy of your diagnosis, but, insomuch as the operation necessitates an anesthetic, will you not assure me that my heart is in good condition." All the physicians located the heart by percussion in its conventional position. "Now, gentlemen," remarked the patient, after all the physicians had agreed on the area of heart dulness, "permit me to question the infallibility of your diagnosis and to announce, as this radiograph of my chest will show, that my heart is located on the right side and that I am in consequence a victim of what is technically known as dextrocardia."

After many years of experience in teaching physical diagnosis to physicians the writer is impressed with the fact that errors in percussion are most frequently perpetrated not because of a faulty execution, but owing to a failure to recognize nuances in sound.

The interpretation of sound is a matter of education, otherwise the notes of the musician would be cacophonous and the messages read by the telegrapher would be erroneous.

The writer has constantly endeavored[1] to eliminate certain factors which are elicited in percussion and conduce to so much confusion in interpretation. This refers in all cogency to certain ventral[2] and pulmonary areas[3] of dulness which are constantly present in certain diseases.

Topographic Percussion.—Percussion of the chest or abdomen produces a sound which is the product of the vibration of the air-containing tissues and the thoracic and abdominal walls. It is the summation of this vibration which interferes with the elicitation of the dulness of the airless in juxtaposition to the air-containing organs. By eliminating one factor of vibration the topographic definition of solid viscera would be more easy of attainment.

Much ingenuity has been displayed by clinicians in devising new methods of percussion, but unfortunately an ideal method has not thus far been attained. By means of the method presently to be described uniform results can be achieved by the merest tyro and this uniformity in interpretation which can alone dignify a method as scientific is easy of execution.

Method.—This embodies the principle of transsonance and is executed by continuous or intermittent direct percussion (without the interposition of a plexímeter) with the finger at the acromial extremity of either clavicle. In very fat individuals a plexímeter* may be used and the latter struck by aid of a plexor with a soft rubber end. The following results are attained with the patient standing (the writer's usual method of examination).

In the execution of the method cognizance is taken of the following components which make up the maneuver: (1) Dulness; (2) palpatory percussion; (3) auscultatory percussion.

Dulness.—In delimiting the heart, aorta, liver, spleen, or kidneys, or in the detection of lung or abdominal dulness, one executes a series of percussion blows with the finger of one hand at the acromial extremity of either clavicle and with the finger of the other hand moderate pressure is made. The approach to an organ or area of dulness by the latter finger is executed as in conventional percussion. The moment that an area of dulness or the border of a solid organ is attained, a conspicuous, easily recognized dulness is heard which the striking finger also appreciates.

Palpatory Percussion.—Striking the acromial extremity of the clavicle as before, the finger of the other hand approaches the borders of the heart in an *intercostal space* and the moment the border is attained (if the patient is not too obese), a slight impact of the cardiac border is demonstrable to the palpating finger provided the clavicular blow is sufficiently strong. The sensation is not unlike that in ballottement. It is surprising with what accuracy the right and left borders of the heart can thus be defined. The orthodiagraph proves the correctness of the method. The lower liver border in the parasternel, mammary, and axillary lines may thus be defined. The splenic borders are similarly demonstrable.

Auscultatory Percussion.—Percussing the clavicle as before, one approaches the solid organ or a dull area with a small bell of a stethoscope and when the border of the organ is attained there is an immediate transition from resonance to dulness.

In demarcating any of the areas of ventral or pulmonary dulness (by this method) peculiar to disease by the "electronic method of diagnosis,"[2] the results are most striking. Shifting the patient from a position facing the west to the magnetic meridian and back from the latter to the west shows respectively the transition of dulness to resonance and from resonance to dulness. I have shown elsewhere[4] that visceral tonicity varies with the points of the compass. A relaxed organ will yield a smaller area of dulness than an organ in a state of tone. Any physician can prove the foregoing by percussing the heart alternately with the patient facing west, east, north, and south. To achieve uniform results in topographic percussion it is the writer's invariable rule to execute percussion when the patient faces the geographical west.

The foregoing effects are accentuated by striking the fourth cervical spine directly with a plexor or indirectly with a plexímeter if the subject is obese. The latter maneuver necessitates an assistant. In thin subjects looking from above in a propitious light the repercussive effects may be noted during suspended respiration by direct inspection, viz., borders of heart, spleen, lower liver border, and site of the pylorus.

*A Goodyear soap rubber eraser No. 15 is most efficient as a plexímeter for this purpose.

THE VALUE OF THE SALICYLATES IN THE TREATMENT OF INFLUENZA.

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

FORTUNATELY for us, the epidemic of influenza now seems on the wane in New York and elsewhere. However, it may come again, and probably will. It is therefore not untimely to insist again, upon what I have learned as to treatment of it with the salicylates, especially as to why they are at present the best remedies we have. After trials, I came to the conclusion that the salicylate of ammonium is the preferable salt, and, so far as possible, should always be used as a preventive and curative remedy. As an ammonium salt, it is the most stimulating and disagrees with the stomach least. It eliminates itself, in part at least, through the respiratory passages, and is therefore preferable to the sodium salt. Like all the salicylates, it has a decided antimicrobic action in the blood. When taken into the system in sufficient quantity, and frequently, it prevents, as I believe, the transport of contagion to others. As to the proper dose, and its frequency, these depend somewhat upon the individual and the reaction or effects produced. The essential matter is to get the patient under the influence of the drug in a manifest manner and yet not cause unpleasant results, such as are not uncommon with all the salicylates at times, but less, in my observation, with the ammonium salt than with the sodium salt.

To a sensitive stomach intolerance is obviated with the use of essence of pepsin at the same time. Preferably, and when convenient, the salt should be given in solution. To an adult, from five to ten grains may be given for several doses every two hours. Whether or not the use of a protective vaccine would interfere or neutralize the good effects of the salicylate of ammonium I do not know, but up to date I would prefer not to take them at the same time, on the principle that what is unknown should be avoided, or treated with great prudence. One thing is sure to my mind, *i.e.* that the salicylate of ammonium, both in influenza and acute spinal paralysis in children, has a very pronounced protective and curative effect. It is not a specific, and thus far I know of none, but it is the least objectionable and most effective remedy now known. Science may tell us truly later precisely why it is; art for the while, guided by observation and bedside experience, affirmed a clinical fact of very considerable value.

There is no doubt in my mind at this time that, taken properly and in the beginning of influenza, salicylate of ammonium would save many lives otherwise lost either through the influenza itself or the pneumonia which frequently develops very rapidly.

42 WEST THIRTY-SEVENTH STREET.

Medicolegal Notes.

Professional Judgment in Use of Appliances.—In an action for alleged malpractice the alleged negligence of the physician for which the plaintiff sought to recover lay in the use by him, in an operation, of nonabsorbable silk sutures instead of catgut. The only testimony in the record to show that this was improper was contained in an answer to a single question propounded to one of the plaintiff's witnesses, who testified that a careful surgeon would not use silk in the place where it had been used. On cross-examination he admitted, however, that, where a physician requires a ligature that will hold fast to prevent needless bleeding, he may with propriety use the silk, and he made it clear that his previous answer was based entirely on the conditions as he found them at an operation performed by himself six months after the operation by the defendant. The only other medical witness for the plaintiff testified that the choice between silk and catgut is a matter of judgment in each particular case, and there was no testimony in the record to show that, under the conditions as they appeared to the defendant when he performed the operation, the use of silk was negligence. It appeared from the plaintiff's testimony that he had performed two operations on the plaintiff, that on the first occasion he had had trouble from hemorrhage as a result of the use of catgut, and that therefore he had used silk on the second occasion. It was true that the results of the use of the nonabsorbable silk had proved unfortunate, as the silk caused certain perforations of the intestine, which produced serious trouble, but it was clear that on the second operation the defendant was in a dilemma. The use of catgut had resulted in hemorrhage before, which he wished to guard against, and the use of silk might produce irritation. Under the circumstances, he should not be held liable for what was at most a mistake of judgment in weighing the probable consequences of the different methods that might be pursued. A physician is required to possess only ordinary skill in his profession and to use his best judgment in the exercise of that skill, and, if he complies with these requirements, he is not liable for the nonsuccess of his treatment. Judgment for the plaintiff was reversed and a new trial ordered.—Linn v. Piersol (Cal.) 173 Pac. 763.

Promise to Pay for Professional Services to Another.—In an action for services as physician and surgeon the only question was whether the evidence warranted the court in finding that the transaction between the plaintiff and the defendant created an original or primary obligation on the part of the latter, it being his contention that he was, at most, a guarantor, and that the obligation was void because not in writing. The services were performed for one F. J. Williams, and the plaintiff was called upon to attend him on the 5th day of October. Two days thereafter, according to the plaintiff's testimony, he had the following conversation with the defendant at the Sacramento Valley Hospital:

"I asked him whether he would pay Mr. Williams' bill. I told him I had an understanding he was going to pay the bill, and he said he would. I told him perhaps we had better make the sister feel more easy about the money. When we went downstairs, I repeated the conversation in front of Sister Marie, and the substance was that he was to pay Mr. Williams' bill."

He further testified:

"I made three calls on the 7th; on the 8th three calls; on the 9th there were five calls made; and on the 10th he was operated on by myself, Dr. Johnson and Dr. Wilson. I called on him twice subsequent to the operation; on the 11th I called three times; on the 12th I called four times; and on the 13th three times, the day he died." These services, performed after his conversation with the defendant, were reasonably worth, so he said, the sum of $305, and this was allowed by the trial court. It was held on appeal that it was a fair inference from the foregoing that these services were performed upon the reliance that the defendant would pay, and it was also a fair inference that the latter directly promised to make such payment. This constituted an original contract, with a sufficient consideration for its support. Judgment for the plaintiff was affirmed.—Meyers v. McKillop, (Cal.), 173 Pac. 773.

Military Medicine.

Rehabilitation of the Disabled Soldier in Canada.—In Canada the terms "Occupational Therapy" and "Industrial Reeducation" are employed, the first to denote the work done in the hospitals of the Department of Militia and Defense, which is principally curative but also includes vocational work under the direction of medical officers, that is, the man is given whatever training is considered desirable with due regard to his physical and mental condition. Training given in the wards to such men as cannot leave the hospital is called "Ward Occupation."

"Industrial Reeducation" is the term given to the work undertaken by the Department of Soldiers' Civil Reestablishment, after the man has left the military hospital; this was formerly under the direction of the Military Hospitals Commission. In the development of a policy of reeducation by the Department of Soldiers' Civil Reestablishment, it became apparent that something must be done to prevent reeducated soldiers competing against each other in a certain narrow group of occupations in which training was practicable in the institutions established for that purpose. An industrial survey of the Dominion was therefore undertaken and the country has been divided and subdivided into districts; in each industry an analysis has been made of the different occupations therein, with information as to the kind of work done, the payment, working hours, qualifications required, and so on, and it has been decided to train the men, whenever possible, in shops where they will later be employed, as this gives greater diversity of opportunity. The character of the work to be undertaken is considered in relation to the man's disabilities; for instance, it is determined whether the position at work would aggravate any weakness or disability, etc.

In deciding upon the training to be given to each individual, the vocational officer first considers the man's choice—first and second—his hobbies and natural preferences, and the productivity of and demand for the class of work chosen, leading the man if possible to take up a technical or industrial rather than a clerical occupation. In short, the combined knowledge of the medical and vocational officers is utilized to guide the disabled soldier into a field of productivity compatible with his state of health, which will make him independent in the years to come when people may begin to forget the cause of his disability and the service he has rendered his country. When training is completed and the man placed in a position, every effort is made to keep in touch with him by means of a "follow-up" system. At the present time, training is given in occupations to the number of 179. It has been found in Canada, as well as in England, that the positions of chauffeurs and clerks are those most frequently chosen, and this is so much so that whenever possible the man is persuaded to take up some other line in which the demand for his labor will be greater.

One of the difficulties in the problem of rehabilitation of the disabled soldier is to bridge over the period between convalescence and readjustment to civilian life. The public, and particularly the employer, can do much by a little sympathy and kindness toward the soldier who is trying to adjust himself to his new environment.

The following figures give some idea of the work being done in Canada: On August 1, last, 5045 courses in industrial reeducation had been granted. In the curative workshops, 1991 convalescents were working at that time, and 1990 men were taking courses in industrial reeducation. During the month of June, 1743 men attended classes in occupational therapy conducted by the Department of Soldiers' Civil Reestablishment in military hospitals.

Cases of pulmonary tuberculosis are discharged from the army as soon as diagnosed and their care and treatment are undertaken by the medical branch of the Invalid Soldiers' Commission. The duties of this branch include also the medical care of all men undergoing industrial reeducation, the dental care of such men, and also of discharged soldiers suffering from dental defects due to war service, the care of the permanently insane, the epileptics, feebleminded and incurables, as well as cases requiring prolonged institutional treatment. Tuberculosis patients, of course, are treated in the various sanatoria throughout the country, and the insane are sent to the provincial asylums. The case of the feebleminded and epileptics is still under consideration; it is probable that they will be given institutional care and one institution has already been established for their treatment; others will probably be opened and it is possible that a farm colony may be established. Homes for the care of incurables are to be established in each district, one —Euclid Hall—has already been opened in Toronto. In case of recurrence of war disability, the patient will be sent to an Army Medical Corps or local hospital and taken on the strength of the Invalid Soldiers' Commission, *i.e.* he will receive I.S.C. pay and allowance and be treated by I.S.C. medical officers, the great majority of whom have seen active service during the war and therefore are familiar with the soldier's problems.

In Alberta a 300-400 bed sanatorium is in process of construction at Bowness, about 8 miles from Calgary. This will later be expanded to accommodate 500 tuberculous patients. It is the intention to build a recreation building with theater, a billiard room, library, post office, and vocational training shops. When no longer required for military patients, these buildings will constitute a sanatorium for the civilian needs of the province. At the Conference of Medical Superintendents Caring for Tuberculous Soldiers in Canada, last May, it was the general opinion that it was not desirable to establish a course in motor mechanics for patients suffering from tuberculosis, and it was resolved that a committee be appointed to consider what courses of training were suitable for such patients. It was pointed out that the wage earning capacity of the tuberculous soldier was of the greatest importance, as

in order to maintain his efficiency and as high as state of physical condition as possible such a man required a higher standard of living than the average. It was also thought inadvisable to plunge a man into civilian life at once upon leaving the sanatorium. The question of a Central Research Laboratory for the Dominion was brought up at this meeting. It was pointed out that advantage ought to be taken of the present opportunity for research work. It is probable that a Central Laboratory will be established near Toronto with facilities for research in tuberculosis. In the meantime, it may be possible to make arrangements with University and Provincial Health Laboratories to carry on some of this work.

A new branch of the Invalid Soldiers' Commission has been formed which is called the Orthopedic and Surgical Supplies Branch, which has charge of all matters relating to the issuance and repair of artificial limbs and other appliances. The headquarters of this department is in Toronto, but branch depots are being established at Calgary, Edmonton, Victoria, Regina, and Saskatoon.

Treatment of Tetanus and Gas Gangrene.—Col. A. Primrose of Canada recently delivered his presidential address to the Academy of Medicine of Toronto, in the course of which he discussed the treatment of tetanus and gas gangrene and pointed out that the incidence of tetanus in this war has proved the value of the experience which has been gained in the treatment of the wounded. A study was made of the number of cases which occurred in home hospitals among the wounded returned from France. In October, 1914, there were 32 cases per 1000 wounded. In November, 1914, there were two cases per thousand, and during the subsequent two years the average number per month was only one per 1000 wounded. There were several factors which produced a very large number of cases of tetanus in September and October, 1914, such as the character of the soil in the fighting area, the heavy fighting with its heavy toll of wounded, the difficulty of properly caring for the wounded, etc., but it was not until the middle of October that prophylactic inoculation was introduced in anything like a complete scale. Immediately a remarkable fall in the incidence of tetanus occurred, the number affected being less than one-thirtieth of that prior to the employment of prophylactic treatment. But experience has led to further conclusions and it has been found that antitetanic serum is curative as well as preventive. Large doses of the serum are given by the intrathecal route immediately on tetanus manifesting itself. From 50,000 to 100,000 units may be given in the first few days, the object being to saturate the body with antitoxin as quickly as possible. The curative value of such treatment has been determined in many instances. Then again it has been learned that the bacillus of tetanus may remain incapsuled within the tissues for prolonged periods and may, independently of any fresh transmission, cause a recurrent attack. This is very prone to occur as the result of any secondary surgical operation and in certain specific instances has brought about fatal results.

Knowledge of gas gangrene, its etiology, prevention, and treatment has been greatly advanced. Its spread along lymph spaces and the invasion of damaged muscle fibrils; the absence or scanty occurrence of leucocytosis; the proliferation of epithelium with thrombosis of veins resulting in rupture of vessels with extravasation of blood and rapid spread of infection, and the characteristic appearance of certain cases in *x*-ray plates are some features of this infective process regarding which knowledge has been greatly increased.

The treatment consists first in prophylaxis, encouraging personal cleanliness in the soldiers, treating trench walls with slaked lime, etc. Every wound should be looked upon with suspicion and should be submitted to immediate and thorough cleansing, the use of antiseptics and the removal of all foreign matter. Particular attention is paid to the removal of all lacerated muscle tissue and all fragments of bone and the securing of complete hemostasis. If gas gangrene supervenes the entire wound is freely opened up in all its ramifications, all dirt and foreign matter are sought for and carefully removed. Hematomata which may harbor infection are eradicated, all contaminated muscle tissue is widely excised, and hemorrhagic oozing is carefully checked. Free incisions are made in the long axis of the limb, all tension is relieved and the wound is left freely open avoiding all pressure and possible constriction of blood-vessels, free drainage is provided and the wound irrigated with a potent antiseptic. If amputation is considered necessary the flaps are left widely open without suture.

The results obtained by such treatment may be illustrated by those published by Ivens: of 464 cases of gas infection, 42 were fatal, 25 died from gangrene, 4 died from tetanus and the rest from severe injuries which they had sustained. When the gangrene was limited to a group of muscles it was possible in 41 cases to do a local excision, of these 33 recovered. Amputation by the open method and with lateral skin incisions was done 68 times, and 48 of these recovered.

The Diagnosis of Death.—Some soldiers wounded or suffering from shock are brought to the surgeon apparently dead, and, of course, if there is any doubt in the matter, it is essential that the true facts of the case be established. In many instances it is not easy to make a certain diagnosis, and owing to the severe press of work thrown upon a medical officer after an engagement perhaps, on occasions, he may be somewhat too apt to recognize the similitude of death as death itself. Some of the medical officers also who have been drawn from civil life have not had much experience and are not likely to endeavor to distinguish between apparent and real death. Dr. A. Satal, a French medical officer, some time ago contributed a paper dealing with the diagnosis of death in the firing line to the *Medical Press*. In this he points out that Laborde recommended for the treatment of apparent death the practice of rhythmic traction of the tongue and stated that the procedure was an absolutely unfailing test, its failure to induce respiration promptly proving that death had already taken

place. Satal gives another diagnostic means. This, formulated by Itard, consists of a subcutaneous injection of fluoresceine at some point of the surface of the body. If some few sparks of life remain, that is if the circulation has not been entirely abolished, this substance is absorbed by the blood and carried round with it, and as it is remarkably diffusible it soon succeeds in impregnating all the tissues. The resulting coloration is readily appreciable, especially on ocular surfaces. When fluoresceine acts in this way it encourages the efforts of the medical attendant who will then direct the assistants to proceed with their manipulations.

In civil life such tests have their value but under the conditions of warfare prevailing in Europe, at the present time, the need for their utilization is obvious. There are numerous cases of syncope from shock brought about by the explosion of shells and by gassing in which death is exactly simulated. There have been also cases of wounded men who were apparently dead. Satal asserts that in several instances, by the employment of one or other of these tests, he and his colleagues have been encouraged to persevere in their efforts to stimulate the vital spark, and by means of this persistence to save the lives of soldiers apparently dead.

The After-Effects of Wounds of the Chest and Their Treatment.—Lieut.-Col. John Meakins and Captain T. W. Walker, C. A. M. C, discuss this subject in the *Canadian Medical Association Journal* for October, 1918, and point out that from available statistics the fact is apparent that injury to the chest is not necessarily a conspicuous factor in invaliding soldiers from the army. Even when they are discharged on account of the results of some such injury, they are still capable of doing a considerable amount of work each week in a civilian occupation. Among those patients who are not discharged as permanently unfit, there is a goodly percentage who eventually return to full duty with little or no impairment in the degree of physical exertion which they are able to accomplish. The conclusions drawn by the authors are as follows: (1) Deformity of the chest wall is a very important disabling after-effect of gunshot wounds of the chest. (2) The deformity follows most frequently prolonged involvement of the pleural cavity. (3) The early and persistent evacuation of fluid from the pleural cavity, either by aspiration or by operation, is of great importance in preventing the development of the deformity. Especially is this so in cases of hemothorax. (4) The early uses of special exercises is beneficial in preventing or overcoming this deformity. (5) The prognosis in this condition is exceptionally good under suitable treatment.

The Health of the Army.—With influenza out of the reckoning it could be said that the army was never physically so fit in a period of war as at the present time. The report of the Surgeon General for the week ending October 29 gives the malaria rate in the home forces as 1.51 per thousand; in the army in France it was only 0.64. The dysentery rate was 0.44 in the home camps; in France 3.97. The typhoid rate at home was 0.13 for the week, and in the American Expeditionary Forces only 0.03, which is very striking. Measles furnished the highest rate; 28.54 among the troops in the United States and 6.14 in France. There was very little scarlet fever, the rates being 9.57 in this country and 0.63 in France. Between September 13 and October 29 there have been 310,429 cases of influenza in the home forces. No less than 50,000 of these cases developed into pneumonia, which now constitutes the greatest menace to the American soldier. A vaccine prepared as a preventive of pneumonia by the Rockefeller Institute at the request of the Surgeon-General of the Army was recently administered to 12,000 volunteers at one of the camps at a time when pneumonia (not of the influenzal type) was more prevalent than usual. These men were to go overseas in ten weeks and during that time they were all immune. Some doubt is expressed as to whether the vaccine is effective against pneumonia occurring in influenza.

Red Cross Work Will Go On.—George E. Scott, general manager of the American Red Cross, announces that the Red Cross will continue its military relief work after the consummation of peace, until demobilization of the American forces is completed. The American Red Cross will in all probability be called upon to direct rehabilitation and reconstruction work in the war areas following the declaration of peace. An official report states that within forty-eight hours after the Austrians evacated Vittorio, Conegliano, and Oderzo, relief was distributed to the civilian population by the American Red Cross, and despatches from Rome state that the prompt measures taken by relief units prevented great suffering.

Red Cross Establishes New Activity.—Among its other activities the American Red Cross in France has established a Bureau of Medical Research and Intelligence Department, of which Lieut. Col. Alexander Lambert is the Chief. The divisions of the bureau are: Medical Library, Medical Publications, Medical Research, and Medical Intelligence Bureau. The Department undertakes to supply the field, camp, and evacuation hospitals with medical books and journals and also to reply to individual requests as to the most recent developments in war medicine and surgery. Major Thomas H. Halsted is Chief of the Medical Intelligence Bureau, which is occupied especially with looking up literature, reports of commissions, etc. It responds at once to all requests for information on medical and allied subjects asked for by any medical member of the American Expeditionary Forces or the Red Cross. An index is kept of all articles relating to War Medicine and Surgery, and also abstracts of the more important ones. Dr. Emil Mayer has been appointed representative of the United States for this Bureau. Writers of original articles on war subjects are requested to send two reprints thereof as soon as possible to the Medical Intelligence Bureau, American Red Cross, 9 rue de Mont Thabour, Paris, France.

King Gives Home to Red Cross.—King Albert of Belgium has presented his beautiful home adjoining the Pavilion Henry IV, at St. Germain,

for convalescent American officers. Henry P. Davison accepted the gift in behalf of the American Red Cross.

The American Army Laboratory in France.—The central Laboratory of the American Laboratory in France was formerly one of the large Pasteur institutions in central France, but has been turned over to the Americans with extensive grounds, where temporary buildings are going up to make provision for the increasing work. One of these buildings equips transportable field laboratories, one hundred of which have thus far been sent out. The laboratory is extending its research work into every branch of military medicine and surgery. It announces that at the present time it is making important advances in the investigation of shock following shell wounds and also in regard to the effect of gas attacks on the different organs and tissues of the body.

Public Health Service Reserve.—A recent bulletin announces the passage by Congress of a joint resolution approved by the President on October 27, establishing a permanent reserve force upon which the Public Health Service can draw in time of emergency such as that presented by the influenza epidemic. This consists of officers, none holding rank above that of Assistant Surgeon General, commissioned by the President for a period of five years, subject to call to active duty by the Surgeon General U. S. P. H. S. When in such active duty they receive the same pay and allowances as are now provided by law for the regular commissioned medical officers in the service. By far the larger part of the reserve to be organized under this act will be on active duty only during times of national emergency, though it will probably be necessary to establish periodic terms of training, so as to better fit the officers for such service. With the passing of the emergency these men will automatically go on the inactive list; always, however, subject to call to active duty by the Surgeon General. Detailed plans for the organization, training and assignment of the reserve officers are now under consideration.

Deaths in the Service.—Lieut.-Com. Frank Pennybacker White Hough, Medical Corps, U. S. Navy, died at sea aboard the U. S. S. *Huron*, on October 27, when the transport was nearing France. He was graduated from the University of Virginia, in 1907, and immediaely entered the Navy. He saw service in China and in the Philippines, as well as in the present war.

Lieut. Robert Kenton McGuffin, M. C., U. S. Army, of Imperial, Cal., a graduate of the Maryland Medical College, Baltimore, in 1911, and coroner of Imperial County, who was ordered to report for duty at Camp Kearney, on October 23, died from pneumonia at his home, on October 20, aged 33 years.

Asst. Surg. Rushmer Christian Christiansen, Lieut. U. S. Navy, a graduate of the State University of Iowa, in 1915, on duty at Mare Island, Cal., died from pneumonia, following influenza in the Naval Hospital at Mare Island, on October 19, aged 28 years.

Capt. Jean Paul Gay, M. C., U. S. Army, of McAlester, Okla., a graduate of the University of Louisville, Ky., in 1908, died at his home, on October 25, from pneumonia following influenza.

Lieut. Wendell James Phillips, M. C., U. S. Army, of Corvallis, Ore., a graduate of Jefferson Medical College, in 1915, died at Camp Lee, Va., of pneumonia following influenza, on October 13, aged 31 years.

Asst.-Surg. Norwin Batte Norris, U. S. Navy, of Memphis, Tenn., a graduate of the University of Tennessee, Nashville, in 1917, aged 27 years, is reported in the *Official Bulletin* of October 14, as missing on the U. S. S. *Ticonderoga*, sunk, September 30, by a submarine.

Lieut. Guy Chaille Haralson, M. C., U. S. Army, of Vicksburg, Miss., a graduate of Loyola University, Chicago, in 1917, died from pneumonia at Fort McPherson, Ga., on October 24, aged 36 years. Before entering the army he was assistant physician at the East Mississippi Insane Asylum.

Lieut. Timothy Joseph Moran, M. C., U. S. Army, of Pittsburgh, Pa., a graduate of the University of Pennsylvania, Philadelphia, in 1905, died of pneumonia, at Camp Greenleaf, Fort Oglethorpe, Ga., on October 17, aged 37 years.

Lieut. Homer E. Van Epps, M. C., U. S. Army, of Sterling, Ill., a graduate of Hahnemann Medical College, Chicago, in 1916, died recently of pneumonia following influenza, at Camp Mills, Long Island, N. Y., aged 31 years.

Lieut. Robert Archie Sherwood, M. C., U. S. Army, a graduate of the University of Oregon, Portland, in 1916, and of the Army Medical School, Washington, D. C., in 1918, aged 28 years; is reported to have died in action in France, on September 17.

Lieut. Carl Bibb Hudson, M. C., U. S. Army, of Montgomery, Ala., aged 30 years, a graduate of the Harvard Medical School, in 1917, died from pneumonia following influenza, on October 2, a few days after his arrival in France.

Lieut. Chester Cameron Wood, Past Assistant Surgeon U. S. Navy, a graduate of Jefferson Medical College, in 1910, on duty on the U. S. S. *Alabama*, died at sea on October 5, aged 30 years.

Lieut. Frank Benedict Rosinski, M. C., U. S. Army, of Cleveland, who had just been ordered to Fort Oglethorpe, Ga., died of pneumonia at his home, on October 21, from influenza.

Lieut. Herman Warner Krantz, M. C., U. S. Army, of Union Bridge, Md., a graduate of the University of Maryland in 1915, died from influenza, at his home, on October 5, aged 27 years.

Lieut. Wilburn Edgar Hampton, M. C., U. S. Army, of Ferris, Texas, a graduate of the University of Louisville, Ky., in 1910, died in Dallas, Texas, on October 21, aged 31 years.

Dr. Tribondeau, Medicin Principal de la Marine, died of influenza in the naval hospital at Achilleion, Corfu, at the age of 46 years. He was formerly professor in the École de Service de Santé de la marine, then head of the laboratory of bacteriology of the fifth arrondissement maritime and was then called to direct the bacteriological service of the Hôpital de l'Achilleion. Fatigued, ill ,and on the point of returning to France when the influenza broke out among the crews at Corfu, he insisted on remaining on duty to attend the sick until he was stricken by the disease.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

CEREBRAL ABSCESS AS A COMPLICATION OF BRONCHIECTASIS.

OUR knowledge of pathology teaches us that a change in the histological structure of the bronchi is essential in order that bronchiectasis shall occur. Therefore, it is for the pulmonary symptoms, or rather those of the bronchial tubes, that the patient seeks medical advice. Usually the patient is an adult, who reports numerous attacks of bronchitis with frequent coughing paroxysms in his antecedents. Expectoration is free and apt to be purulent and fetid, occurring in the morning and repeated several times during the day. There may have been hemoptysis or blood-stained sputum. Percussion gives dullness or, on the contrary, a cavernous note may be elicited if the cavity is large and superficial. Auscultation reveals the signs of cavities which will vary according to the degree of repletion of the latter.

These patients are frequently suddenly seized with chills and a rise in temperature, nausea with occasional vomiting, and always there is intense headache, often remittent and increased by pressure on the cranial bones. The pulse is almost always slow, there is photobia, with unequal pupils and tinnitus aurium. Stiffness of the neck and conjugate deviation of the head and eyes, as well as pupillary stasis are almost constant signs. The meningitic line and idiomuscular contractions are easily made to appear. The subject is always somnolent, answers questions slowly, and finally coma develops. But before this takes place, paralyses occur resulting from a cerebral purulent collection which has destroyed the cortical center or its routes of transmission. This is made evident by hemiplegia or a paraplegia with or without an apoplectiform ictus. Convulsions are common and progressively involve one limb after another. There may be aphasia, especially when the abscess is seated in the left temporal lobe. True motor aphasia is uncommon unless the third left front convolution is involved. The pulse is always slow, likewise the respiration, which proves that there is an increase in the intracranial pressure. There is sometimes a Cheyne-Stokes respiration. The paralytic phase may suddenly develop and last but a few days because the patient dies. When the cerebellum is involved the usual incoordination and staggering occur.

Cerebral abscess of bronchitic origin does not always assume the same clinical form and for this very reason the diagnosis is not always easy. Usually the evolution is rapid, recalling either meningitis or typhoid fever. In the meningeal type the phenomena of excitement are more marked, while the meningitic line and idiomuscular contractions are observed. Sometimes after this phase a remission occurs, to be followed by another phase of excitement, and this condition of affairs may continue until death takes place. This form is very difficult to diagnose and frequently the diagnosis is made only at autopsy. However, when a patient presents a bronchiectasis with meningeal phenomena a cerebral abscess should be thought of.

Another serious form of these cerebral metastatic abscesses is the typhoid variety. There are intense cephalalgia, chill, and prostration. The abdomen is distended and the spleen tumefied. Lenticular rose-spots may appear. All these signs certainly recall typhoid fever, but usually in brain abscess there is less delirium and the rose-spots are not so marked. The process is not always so rapid in its evolution, but on the other hand there is the fulminating form which brutally occurs with apoplectic accidents, convulsions, and death from asphyxia within a few hours in some cases. The latent form of the process is rather uncommon, but it ends in death after alternations of meningeal paroxysms and remissions. Therefore, the diagnosis is usually a matter of difficulty, but a correct conception of the case may be had if one recalls that meningeal symptoms with paralyses and convulsions in a subject with bronchial dilation probably indicate the development of a metastatic abscess of the brain.

THE PREGNANT WORKING WOMAN.

WE are getting away from those days of mid-Victorian modesty when to speak of a woman being *enceinte* was forbidden, and for a woman to go out into the public streets when her contours began to suggest her condition was nothing short of shameless. In fact, one of the stock arguments of the opponents of industrial occupation for women has been that women could not be considered trustworthy economic units as at any time a pregnancy might incapacitate them for many months. The present war has forced the issue to some extent. The military armies have been kept intact at the expense of the industrial ones which has meant that vast numbers of women have been enrolled. Many of these have been married women, and as England is not so far from the battle-front the problem of what attitude to take toward these war workers when they became pregnant was soon an acute one. Many employers took the attitude that the employment of expectant mothers would mean a financial loss and moreover

that a woman obviously pregnant should not continue to work day after day in sight of other employees. Fearful of losing their jobs when the money was so much needed to prepare for the expenses of confinement, many of these women, it was discovered, concealed their condition as long as possible and consequently were kept on work unsuitable and even dangerous. A great many others managed to terminate pregnancy in the early months.

During the early part of this year an effort was made to establish some sort of war work which could be done by women in this condition, and in April, 1918, a pre-maternity department was opened at the National Ordnance Factories, Leeds. As soon as a factory employee becomes pregnant she fills in a form of application which is sent to the superintendent of the scheme, who is a woman. She refers it to the factory medical officer for data regarding the number of the pregnancy, time of expected confinement, general physical condition, and date when a transfer to lighter work would be advisable. As soon as they have recorded their pregnancies they are transferred to work which does not require any heavy lifting or other severe physical exertion. At the end of the fourth month, or earlier if necessary, they are put at such light work as gauging and assembling fuse parts and are taken off night work altogether, working from 7.30 to 5.30 with breaks for meals. At the end of the seventh month another transfer is made, and these women are put at making and mending clothes from 9 to 5. The last hour of the day is devoted to preparing garments for the expected baby, which is done under the direction and help of the sewing depot forewoman. They make their own arrangements for attendance during confinement and can work up until the time labor pains start, if they wish.

It has been found that this arrangement works very well. Unmarried girls are treated the same as married women and thus a large part of the incentive to conceal pregnancy is lost. Miscarriages and abortions are rendered infrequent instead of being all too common. Furthermore, the health of the expectant mothers has been good and dystocia less frequent. The employers themselves report that from a business standpoint the scheme has been a success. So perhaps this humanitarian attitude toward the problem of the pregnant working woman will survive the declaration of peace and become part of civilization.

ORIGINAL RESEARCH FOR THE YOUNG PHYSICIAN.

Among the rainbow-hued dreams of youth which approaching age dims to ashen gray is the phantasy of original medical research. Who of us has not pictured himself as the discoverer of some germ, of some disease named after him, a diagnostic sign or a method of treatment which will perpetuate his fame and inspire some twenty-first century medical historian. Later on we find out our time is pretty well taken up with our daily rounds, our medical meetings, dispensaries, social obligations, medical periodicals, and occasionally even a little recreation, so that the dream of doing something startling is shoved further and further back in our minds and is finally represented only by an occasional paper in our favorite medical journal. Moreover, the sober reality is that even those who set out to do research, who gird up their loins so to speak, and deliberately court this goddess, seldom achieve such world-shaking results. Indeed the paucity of the results obtained and their lack of practical value are characteristic of nine-tenths of all medical research, and the pharmacologist of this year upsets the conclusions of him of last year.

Perhaps a reason for this state of affairs may be found in the conventions which govern medical research. In the first place, so many great discoveries have been made in laboratories that the young investigator naturally turns his attention first of all to this field. Here he seeks the advice of someone known to be doing what is euphemistically termed "research." Then it often happens that long hours of earnest labor are spent in pursuing some problem of only academic value or in the achievement of some result of inframicroscopic importance. In the wards of hospitals we perhaps come into closer touch with the triad which is present in all medical problems—the patient, the disease, and the physician. Here the limit to the clinical investigation of disease seems to have been reached, a result which is not surprising to anyone who has made rounds through hospital wards year after year, and seen the eternal sameness of the cases. In the hope of variety or novelty we acclaim each new diagnostic instrument hoping that it will be the key which will open to view new vistas of medical science.

An important and interesting field is being neglected in this attitude. Let us not forget that when we occupy ourselves with the laboratory, the ward, and the post-mortem room we are studying disease after it has gained a foothold in the human organism, in other words, in its latter stages. But what is being done to study it in its insidious beginnings when perhaps it can be prevented? The out-patient department of the hospital offers a large field for the study of preventive medicine. Here, if a young physician really wishes to conduct some worth-while researches, is a fertile field. Many of these patients when they first apply for treatment present symptoms which are entirely subjective. What is the origin of these symptoms, their value, prognosis, and treatment? Heretofore the general practitioner has been the one who has had the greatest opportunity to study disease from this standpoint and he has been prevented from investigating the subject properly for two reasons: first, because

he is too busy, and second, because his habit of thought is that research of value can be done only in the laboratory and hospital ward. Let us take for example, any of those symptoms for which people consult physicians, people who are not really ill, but who wish to know what their pains and discomforts mean. They will ask the physician what causes such and such a symptom, what it means, what will happen if it is not treated; will it recur if treated, and so on. A conscientious physician, wishing to answer such questions honestly, may turn to his library and search and search in vain. What he finds will convince him of the necessity and value of medical research along these lines.

Here then is a field lying fallow for the ambitious young physician. Let him take one symptom, such as irregularity of the heart, collect all the patients he can find showing this symptom, examine them frequently for twenty, thirty, or forty years and then publish a monograph on the subject. Sixty-eight copies of this will sell, he will get four-line reviews in all the leading medical journals, and two hundred years from now his name will appear in a footnote on page 417 of a history of medicine.

INSIPID DIABETES OR SO-CALLED ESSENTIAL POLYURIA.

SINCE Claude Bernard's researches on experimental polyuria, induced by pricking the floor of the fourth ventricle in the rabbit, and the discovery of the phenomena of the internal secretions, two principal opinions have been emitted concerning the origin and nature of insipid diabetes, namely, the nervous theory and the glandular theory. The partisans of the latter, basing their theory on the frequent coexistence of hypophyseal disturbances (infantilism, acromegaly, the adiposogenital syndrome, etc.), as well as on experimentation and therapeutic results, attribute a preponderating part to the hypophysis. The posterior lobe has been particularly incriminated and above all its middle portion or pars intermedia.

The study of clinical data and the results of therapeutic and physiological research have not been of a nature to determine positively either the nature or the origin of the disturbances noted. In fact that it is often difficult to localize exactly a lesion involving the organs at the base of the skull and in the cases in appearance the most limited in extent, it is quite impossible to make abstraction of regional reactions, be they from irritation, compression, or invasion. Injections of extract of the hypophysis have also proved themselves too unreliable, and physiologists have raised their voices against the idea of a too absolute specificity of organic extracts.

Experimental work, especially that undertaken by Harvey Cushing, appeared more demonstrative and for an instant it was thought that the hypothesis of the glanular theory of hydruria had become a fact. But the preceding objections have retained all their value, for it is to be recalled that Aschner, controlling Cushing's experimental work, found that in most of the cases there was a diffusion of the lesions which took away the greater part of the value of the experiments. The temporary character of the polyuria thus obtained forbids the symptoms being referred to the permanent lesion resulting from the removal of the hypophysis.

The more precise experimental researches made under a strict pathological control permitted Camus and Roussy, by eliminating all causes of error, to eliminate once and for all the primary part played by the hypophysis in the production of the syndrome. Operating on dogs by the buccal route, these writers were able to obtain a very considerable polyuria after partial or total hypophysectomy, but their early results appeared at first paradoxical, because in two bitches who had undergone hypophysectomy one presented an abundant polyuria while the second animal did not offer a trace. Researches undertaken to control these results showed that ablation alone of the hypophysis was without result, but on the other hand a lesion, no matter how minute, of the nervous structure situated immediately in front of the infundibulum resulted in the production of a marked polyuria, usually temporary, but occasionally permanent. These results were particularly distinct in cases where the integrity of the hypophysis had remained complete and these latter data would seem to prove beyond question that the hypophysis has nothing to do with the production of polyuria.

From pathological findings it would appear to result that the cerebral lesion susceptible of producing the syndrome in question must be seated in the opticopeduncular region at the level of the gray matter of the tuber cinereum in the neighborhood of the infundibulum. The lesions located in front of or behind this area do not ever give rise to polyuria.

In the very great majority of cases the regulating mechanism of the amount of water of the organism is not involved and the animals experimented on compensate almost exactly the loss sustained. In one experiment this mechanism was wanting and the animal died, and if this experiment was more frequently resorted to it might militate in favor of the area very close to the center of polyuria and that of the regulation in the content of water in the organism, a center which was first hypothetically suspected by Camus and Roussy. The pathogenesis of the syndrome is as yet poorly understood, but reference should be made to the similitude of action existing between the optopeduncular lesion and division of the splanchnics. Undoubtedly these nerve bundles represent the centrifugal track followed by the excitation, while the infundibular center may be regarded as the inhibiting center.

Fatal Septicemia of Buccodental Origin.

Although we hear much to-day of dental sepsis, these cases consist chiefly of suppurative local processes, sometimes remotely situated, referred to, often hypothetical, root abscesses. There is frequently difficulty in tracing effects to causes in these cases, and some conservative members of the profession profess to believe that these alleged dental infections often exist only in the minds of faddy practitioners. But there is no element of uncertainty in three cases of fatal sepsis reported by Dufourmentel and Frison in *La Presse Médicale* for August 8. In the first case a pyorrhea alveolaris was complicated by acute gingivitis and cellulitis of the neck—a condition evidently identical with Ludwig's angina. A study of the teeth failed to show any dental focus of suppuration. The phlegmon was freely incised and drained, but death occurred from acute sepsis. Autopsy did not illuminate the case further but the bacteriology was of the highest interest, for the offending organism appeared to be an anaerobe closely resembling the bellonensis, one of the most potent causes of gas gangrene. The microbe evidently induced a specific edema with a certain amount of sphacelation. In the present case no gas appears to have been formed during life, nor in an inoculated guinea pig. In the second case there was a dental abscess, evidently an ordinary gum boil connected with an upper wisdom tooth, which was at once extracted. The immediate results were good but in two weeks there was a renewed formation of pus *in situ*, and it soon became evident that a phlebitis was developing. The appearance of exophthalmus showed infection of the cranial sinuses and autopsy revealed that the cavernous, coronary, and some of the affluent sinuses were thrombosed. The third patient had a dental osteoperiostitis without extensive local reaction, death taking place from pure sepsis. Autopsy threw no further light on the case. Extraction of the roots had given vent to much foul pus and there were several pockets of pus in the immediate vicinity, but no extensive cellulitis, phlebitis, or other local mischief. Hemoculture in this case was negative. These cases of buccodental sepsis are in sharp contrast with the insidious and nonexplosive type so often mentioned at the present day.

Mumps Pancreatitis.

The opinion is sometimes ventured that certain mysterious cases of fatal diabetes in children are due to pancreatitis which originated as a metastasis in epidemic parotitis. Naturally this thesis is hard to sustain. In the *Correspondenz-Blatt für Schweizer Aerzte*, of September 14, Zimmerli takes up the symptomatology of mumps pancreatitis. It is clear that if this lesion can be diagnosticated at the time and such cases carefully followed up, the end results can be partly forecast; for a chronic interstitial pancreatitis is susceptible of recognition through the character of the stools and diabetes could hardly be avoided if the condition were sufficiently progressive and destructive. Zimmerli's case, however, occurred in an adult and in his remarks he does not allude to the problem of consecutive diabetes. It is common observation that epigastric pain occurs in certain cases of mumps, in about 25 per cent., while tenderness to pressure may often be elicited at or around the epigastric area. Other symptoms referable to the gastrointestinal tract, are seen in all general infections and cannot be straightway attributed to a pancreatitis. Generally speaking in all cases of acute pancreatitis the symptoms are not clean cut. Certain clinicians admit the existence of a benign pancreatitis with mumps with symptoms of spontaneous pains in the upper abdomen, vomiting, resistance in the epigastrium, fever, and relatively slow pulse. Several writers report expressly that there is no glycosuria at the time of the inflammation. The author's patient was a soldier of 26 with double parotitis and right orchitis. There was no general reaction at first. On the sixth day spontaneous pains were felt in the upper abdomen. This was followed by repeated attacks of vomiting and later by high temperatures. The stools showed pancreatic insufficiency. The left testicle now became involved. The general reaction subsided after a few days. By palpitation an enlarged pancreas could apparently be recognized. Sugar was absent throughout from the urine. The recovery was apparently prompt and complete.

Variolization of Vaccinated Heifers.

Students of the history of vaccination will recall that at an early period attempts to immunize human subjects with recently variolized calf vaccine led to the development of true variola in the vaccinated subjects. This experience brought about the custom of inoculation from calf to calf until a virus could be obtained which could be depended on for safe vaccination of the human individual. So far as we know, Jennerian vaccination has never been accused a second time on this count. Recently, however, an analogous phenomenon has been recorded by Wurtz and Huon before the Académie des Sciences of Paris, reported in *La Presse Médicale* of September 21. In general, eight days after the Jennerian vaccination of a heifer, the latter is considered to be immune to variolization; this has been attested by Kelsch, Camus, and Tanon. Nevertheless the present authors have succeeded in variolizing vaccinated calves beyond this eight-day limit. Proof is furnished by the normal clinical evolution of variola, backed up by the character of the eruption, the pathological anatomy of the lesions, and the positive results of inoculation of monkeys and rabbits. The Jennerian virus can immunize against vaccina, but for a brief interval the organism is sensitive to variolization. This simple criterion suggests in the minds of the authors that the two diseases have separate causations. It may be added that the serum of variolized animals could very probably be employed in the serotherapy of variola.

Magnesium in the Treatment of Cancer.

Recently a French surgeon announced that for a considerable period he had been using magnesium internally as a postoperative remedy for cancer. It was also pointed out that foods rich in

magnesium could be used under the same circumstances. The surgeon did not go fully on record, but his results appeared to be encouraging. From quite another angle the subject came up in a recent sessions of the Paris Academy of Medicine. Regnault had noted the effects of the magnesium salts when used locally on certain warts. With this as a starting point, together with the fact that the defensive zones about neoplastic tissue are magnesium-bearing, the author began the use of magnesium hydrate and silicate internally—from 20 to 25 cgm. of each twice daily. He tested this treatment in papilloma, epithelioma, and inoperable cancer. It must be remembered that silica is one of the alleged favorable remedies in epithelioma and is or was used extensively in the Czerny Cancer Institute as an internal as well as external remedy. Regnault reports excellent results in papillomatous formations and superficial epitheliomata, while in inoperable cancer he claims arrest of growth and relief from burdensome symptoms. After operation he administers inwardly the silicate of magnesium in the aim of preventing recurrence. Something depends on the mode of exhibiton because the response of the organism to a drug may be such that its good potentialities may be sacrificed. He therefore gives the remedy five days and then skips five.

News of the Week.

After Care of Influenza Patients.—The New York Health Department, in order to detect any ill after effects in those who have suffered from influenza and pneumonia, began, on November 11, to make physical examinations of such persons at the different relief centers throughout the city, where physicians of the department are stationed. Food for the extremely needy will be provided at these centers as an emergency measure. From a cursory examination of the death certificates the indications are that 2000 young children are orphans and that many of these are homeless. The Health Department is endeavoring to find good homes for as many of these children as possible. The closing ban has been lifted from all but a few sections of Pennsylvania. The total number of deaths from influenza and pneumonia in the State of Pennsylvania, since October 1, is 37,424. St. Louis is now in the throes of the epidemic. The Mayor has issued an order closing all business establishments in the city that are not essential to the prosecution of the war for a period of five to seven days on account of the influenza.

The Alvarenga Prize.—The College of Physicians and Surgeons of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about $250, will be made on July 14, 1919, provided that an essay deemed by the Committee of Award to be worthy of the Prize shall have been offered. Essays for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten and if written in a language other than English should be accompanied by an English translation. Essays must be received by the Secretary of the College on or before May 1, 1919. Each essay must be sent without signature but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in the possession of the College. Communications may be addressed to Francis R. Packard, Secretary, 19 South 22d Street, Philadelphia, Pa.

The Medical Association of the Greater City of New York will hold its regular meeting in the New York Academy of Medicine, at 8.30 P. M., Monday, November 18. The program includes a paper on "End Results in Tuberculosis Treatment by Tuberculin," by Dr. Henry L. Shively, and one on "The Food Factor in the Causation of Health and Disease," by Dr. Joseph E. Winters, which will be discussed by Drs. Thomas S. Southworth, Graham Lusk, Warren Coleman, R. Cole Newton, E. H. Bartley, and A. F. Hess.

Dr. W. T. Slayton of Morrisville has been appointed to the Vermont State Board of Health to fill the vacancy caused by the decease of Dr. Charles S. Caverly of Rutland.

Dr. Nathan E. Caldwell has been appointed health officer for Burlington, Vt., to succeed the late Dr. F. J. Ennis.

Dr. Walter B. Swift of Boston has been appointed Instructor in Speech Disorders in the Cleveland Kindergarten Training School, where he will train teachers to take speech correction into all the infant schools of Cleveland.

New York Infirmary Fund.—The campaign to raise $200,000 for the New York Infirmary for Women and Children ended on November 9, with a total of $120,398. The Executive Committee will, however, carry on the campaign until the full amount is raised.

Dr. Hanson S. Ogilvie has removed his office to No. 2020 Broadway, near Sixty-ninth Street, New York.

Department of Labor Extends Welfare Work.—An announcement from Washington states that the Department of Labor has taken steps looking to the establishment of uniform working conditions in all districts of the country. There will be three branches of the new service, industrial, hygiene, and medicine, which will direct the formation of sanitary health codes and will be supervised by the United States Public Health Service, the Division of Labor Administration, and the Division of Safety Engineering. The National Safety Council and the Bureau of Standards have agreed to cooperate with the new service.

Polyclinic Hospital Transferred to Columbia University.—At the meeting of the trustees of Columbia University, held on November 4, it was announced that the trustees of the New York Polyclinic Hospital had proposed to transfer the property of that institution to Columbia University, "to be maintained and perpetuated for the public service and research in medicine and surgery." The trustees of Columbia University, in response to this offer, adopted resolutions receiving with grateful appreciation the proposal

of the trustees of the Polyclinic Hospital and appointing a sub-committee to arrange the detailed terms and conditions of accepting the offer. The University will not be able to use the Polyclinic Hospital until after the conclusion of the war, since it is now in the possession of the Government and administered as a military hospital.

Deaths of Foreign Medical Men.—GIUSEPPE GUARNIERI, professor of pathology at the University of Pisa died on August 15 last. Born in 1856 he received his medical degree at Rome in 1882. In 1888 he secured the chair of pathology in Pisa. His duties comprised normal and pathological histology, general pathology and bacteriology. His industry was prodigious and the discovery soon after his assumption of duties of Koch's bacillus gave a direction to his activities. Tuberculosis and malaria took up much of his time and he was the first to succeed in vitally staining the blood. He showed that the pneumococcus could form pus and incidentally cause ulcerative endocarditis. He demonstrated the important part played by the erythrocytes in the coagulation of blood. But amid many minor labors of this sort his principal eminence was in the study of variola and vaccina. He was one of the very few to reach a definite conclusion based on something tangible in the causation of these diseases. These studies began in 1892.

E. LESSER, the incumbent of the chair of dermatology and syphilography in the University of Berlin, died last June. He was for some years the holder of the chair of his special work at Berne, but in 1896 he was called to Berlin, and retained his position there until his death. He was almost a Swiss by adoption and continued to spend his holidays in that country after his removal to Prussia. He was better known as a venereologist than as a dermatologist and his best work was done with the treponema soon after its discovery. Much more modest and retiring than the average Berlin professor he performed unobtrusively a vast amount of first class work in his chosen field.

Obituary Notes.—Dr. JAMES JACKSON PUTNAM died suddenly at his home in Boston, on November 4, aged 72 years. He was graduated from Harvard University Medical School in 1870. He was instructor in diseases of the nervous system from 1875 to 1893 and Professor of Neurology from 1893 to 1912 in his alma mater. Dr. Putnam was widely known as a neurologist and author.

Dr. CHARLES M. SULLIVAN, a graduate of the Maryland Medical College, in 1910, died recently of a complication of diseases at his home in Harrisburgh, Pa., aged 37 years.

Dr. FRANK BAKER of Washington, D. C., died at his home in that city on September 30, aged 77 years. He was a graduate of the George Washington University, Washington, D. C., in 1880, a Fellow of the American Medical Association, professor of anatomy in the Georgetown University since 1883, and for many years lecturer on anatomy at the Corcoran Art Gallery. He was superintendent of the National Zoological Park from 1886 to 1916, president of the Association of American Anatomists in 1897, and once vice-president of the American Association for the Advancement of Science. Dr. Baker was also assistant superintendent of the United Life Saving Service from 1889 to 1890, and editor of the *American Anthropologist* from 1891 to 1898.

Dr. JOHN P. HEYEN, a graduate of New York University Medical College, in 1883, and health officer of Northport, L. I., died at his home in that town on October 30, aged 60 years.

Dr. JOSEPH KAUFMAN of New York died at his home on October 28, aged 30 years. He was a graduate of the Long Island College Hospital in 1910, a member of the American Urological Association, attending genitourinary surgeon to the People's Hospital, and physician to St. Mark's and Mount Sinai Dispensaries.

Dr. MYRON E. STEPHENS, a graduate of the Albany Medical College, in 1888, and health officer of Gardiner, N. Y., died of influenza in that town on October 30, aged 55 years.

Dr. HORACE R. BURNS, a graduate of Gross Medical College, Denver, Col., died of influenza at his home in Denver, Col., on October 14, aged 50 years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

A CASE OF MEDICAL BOYCOTTING—THE MANUFACTURE OF DRUGS IN ENGLAND—THE DESTRUCTION OF RATS IN SHIPS—THE WAR RECORD OF THE LONDON MEDICAL SCHOOLS—UNCONSCIOUS HUMOR—INFLUENZA IN LONDON.

LONDON, October 18, 1918.

DURING July last a case was heard at enormous length against the organization of the British Medical Association, the complainants being certain doctors living in Coventry, who considered that the action of the Association had molested them in their practice and maligned them in their characters. The case was heard by Mr. Justice McCardie, one of the ablest High Court Judges, who sat, by consent of the parties, without a jury. The story unrolled by various witnesses was a very long one, dating back to as much as twelve years ago; the following are the salient points. In Coventry there has existed for many years an institution called the Coventry Provident Dispensary. To this institution persons paid a penny a week, say a dollar a year, in return for medical attention. By the rules of the Association no one was eligible for this semi-charitable kind of medical attendance who was earning more than £2 a week. The Coventry Dispensary had in 1906 20,000 members, that is to say, it possessed an aggregate income of over £4,000 per annum, half of which was shared up between the staff of doctors, from 5 to 7 in number, and half of which paid the establishment expenses and the drugs. A collector who not only collected the subscriptions but canvassed for new members received in lieu of salary a commission in proportion to his success. There were many such medical associations in the country at that time and medical practice suffered a good deal in consequence. Practitioners were urged to stand out against these contract jobs, and accordingly the local medical men in Coventry met the managers of the Coventry

Provident Dispensary in conference and asked to have the rules of the Dispensary altered so that, first, the collector should be paid by a salary; secondly, the medical officers of the institution should have a position in the management of the institution; and thirdly, the wage-limit should be properly enforced and made retrospective in action. For it was alleged that many of the members of the dispensary, though their wages might have been below £2 when they joined, were now in substantial positions and could well afford to pay practitioners properly. The managers of the Dispensary agreed to appoint a salaried collector, for they understood that otherwise their medical officers might be found guilty of canvassing through the collector's agency when they would be removed from the roll of the profession by the General Medical Council. But on other points reform of the dispensary was refused, with the result that the British Medical Association put the institution on a black-list, instructed their members to take no office in it, and to have no dealings either in private or consultant capacity with any medical man who did take such office. Several of the medical staff of the Coventry Dispensary at once resigned their posts, but their places were taken by other medical men in defiance of the fiat of the British Medical Association. A group of these doctors brought an action against the British Medical Association, by whom they had been relentlessly ostracised, on the ground that the boycott by the Association comprised acts of conspiracy, libel, and slander. The case has been maturing for years but only reached the law courts last summer. Mr. Justice McCardie gave the plaintiff doctors a verdict on all substantial counts, and awarded damages variously divided among three medical men of a total sum which fell little short of £4,000. He found the action of the British Medical Association coercive, illegal, and inspired by malice, giving to the word "malice" not the meaning of spite so much as unnecessary harshness in carrying out their program of boycott. The Association, moreover, is to pay all the costs of the lengthy and expensive trial as well as to submit to an injunction.

At the opening meeting of the October session of the School of Pharmacy of the Pharmaceutical Society of Great Britain, Dr. Addison, the Minister of Reconstruction, said that after the war was over it would be necessary to guard against what had been the greatest danger to the country, namely. the acquiescence in the manufacture for us by Germany of numberless things which British trade ought to have made at home. He made no secret of his belief that in a country where no proper training in the applications of science can be easily obtained—a sadly true description of England—the months and even years of absence from laboratories and dispensaries will mean for many men a serious set-back; but he told his audience that the State intended to minimize such results of the war as far as possible. Pharmacologists, as a matter of fact, have done a great deal to help themselves in this plight. For years before the war we had been dependent in this country on Germany for the supply of many medicinal chemicals and certain herbs which provided the basis of a number of essential drugs. We were dependent on Germany for salicylic acid—the discovery of a British physician; for salvarsan and for many convenient forms of local anesthetic. Aspirin we knew how to make, but had no market for our manufacture. Now we have been able to make most of these anesthetics quite successfully, while developing an interchange with America of such commodities; we have turned out a salvarsan as good as Ehrlich's; our novocain is admirable and is being supplied to our Allies, and all over the country laboratories are engaged in restoring to the country a valuable and interesting scientific calling.

The report of Dr. E. W. Hope, medical officer of health to the Port Sanitary Authority of Liverpool, contains interesting figures with regard to the destruction of rats. Next to London and New York, the position of rat-borne infection is more important to Liverpool than perhaps to any port at the present juncture. Speaking of the recent destruction of some 70,000 rats on quays and in the adjoining sewers, in vessels and in warehouses, he points out that to effect the complete destruction of rats on board vessels it is not sufficient to fumigate with sulphur the holds only, and he strongly recommends the use of various gaseous fumes in the saloons also. In United States ports I understand that hydrocyanic acid gas is employed, but the methods of use must require very careful application. Rat-borne infection is going to be a world problem as a league of nations is being welded closer.

The war record of some of the larger metropolitan medical schools is assuming significant importance. Mentioning only the two largest, St. Bartholomew's and the London Hospital Medical College, we find such figures as the following, taken from the records, compiled by the various deans of the schools for the columns of *The Lancet:*

St. Bartholomew's.—From August 24, 1917, to August 22, 1918, 100 joined the Army and 27 the Navy, making a total of 1918 for the four years. There were: Killed in action, 13; died from wounds, 5; died, 4; wounded, 38; gassed, 1; missing, 2; prisoners of war, 10; repatriated from Germany, 3; interned in Holland from Germany, 1; mentioned in despatches, 147. Distinctions: K.C.B., 2; K.C.M.G., 2; K.B.E., 1; C.B.E., 1; C.B., 4; C.M.G., 8; C.I.E., 2; O.B.E., 6; M.E.B., 1; D.S.O., 20; Military Cross, 39; Bar to Military Cross, 1. Promotion for Distinguished Services, 14; Knight of Grace of St. John of Jerusalem, 2; Associate of St. John of Jerusalem, 1; Order of St. Stanislas (3d Class, with Swords), 1; Order of Kara George (4th Class, with Swords), 1; Cavalier of the Order of the Crown of Italy, 1; Order of Star of Roumania, 4th Class, 1; Order of St. Sava of Serbia (3d Class), 1, (4th Class), 3; Serbian Red Cross Decoration. 1; Croix de Guerre avec Etoile d'Or, 1; Croix de Guerre, 2; Order of St. Anne, 3d Class, 1; Albert Medal for saving life, 2; Bronze Medal for saving life at sea, 1; Order of the Nile, 3d Class, 1; T.D. decoration, 2.

London Hospital Medical College.—The completed figures are: Joined, 1470; killed, 96. Honors: G.C.V.O., 1; K.C.B., 1; K.C.V.O., 2; K.B.E., 3; D.B.E., 1; knighthood, 1; C.B., 5; C.M.G., 9; C.B.E., 3; Companions of Honor. 3; D.S.O., 32; D.S.C., 4; 2d Bar Military Cross. 2; Bar Military Cross, 4; Military Cross, 112; Military Medal, 2; Order of St. John of Jerusalem, 4; Hon. Associates of St.

John of Jerusalem, 2; Legion d'Honneur, Croix de Chevalier, 2; Croix de Guerre, 1; Order Crown of Italy, 1; Order of St. Anne (3d Class, with Swords), 2; St. George's Medal, 1; Order of St. Vladimir, 1; Chev. de l'Ordre de Leopold et Croix de Guerre, 1; and l'Ordre de la Couronne, 2 (both conferred by King of Belgians); Order of the White Eagle, 1; Order of St. Sava, 5th Class (conferred by King of Serbia), 1; Jutland Bank Battle Despatch: Commended, 1; recommended, 3; Mentioned in Despatches, 45.

The main significance in the lists lies not in the category of multifarious and oddly named titles or honors, but in the heavy death-roll. There can be no doubt that the doctor's risk, especially that of the young doctor on the fighting front, is as heavy as that taken by any of his brother officers—as heavy indeed as he likes to make it; and this fact, becoming known to all members of the Services, has led to the complete breakdown in old distinctions between combatant and non-combatant commissions. The Navy has just marked this feeling by abolishing the main differences in the uniforms of the executive and engineering officers and the uniform of medical officers.

The claims of widows upon the pension establishment have been in many instances very humorous, and collections of these have emanated from the bureau, the leak being, of course, unofficial. There may seem something heartless in the publication of these unconscious lapses into the jocose when the subject of the letters is so terribly tragic, but on the other hand it must be remembered that those who deal in bulk with the claims of widows for pensions live in such a perpetual atmosphere of depression that they may well be excused if they pay attention to anything that comes before them of a lighter nature.

"I want the congratulation money for the death of my husband."

"I am the holy dependent of the late soldier."

"If you don't send my pension soon, I shall be obliged to lead an immortal life."

"In answer to yours my child was not born in Wedlock but in Brighton."

These are specimens of the "bulls" which can be noted in lay society, but a number of them, especially where it has been attempted to give a medical turn to the communication, become indecent. It appears that "to go to bed with a doctor" is a term for summoning the doctor to the bedside, and that "to cohabit with gentlemen at the War Office" means to communicate with them by letter.

Influenza has again become rife in London, but although the cases are very numerous, the type of disease does not seem to be so virulent as that prevalent in many other large cities.

The High Calory Diet in Spain.—Dr. Salvador Fernandez Alvarez y Cristobal Zaragoza Garcia of Seville calls the attention of his colleagues to the high calory diet of Dr. Coleman of New York. He thinks the account of this diet, as propounded by the American, "sounds good" and is worthy of trial. The Spanish writer is a little weak on nomenclature of proper names, for in one place he styles the American "Dr. Warren" and elsewhere "Mister Warren Colemann."—*Revista Medica de Sevilla.*

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

A NEW WOUND STERILIZER—LOVING CARE FOR THE AMERICAN SILENT CITIES IN FRANCE—NEW INVENTION FOR THE BLIND—NEW RED CROSS HEADQUARTERS IN PARIS—THE HEALTH STATISTICS OF OUR FIGHTERS—THREE AMERICAN WOMEN COMMISSIONED IN THE FRENCH ARMY.

PARIS, October 7, 1918.

MAJOR JAMES T. PILCHER, M. C., U. S. A., of Brooklyn, N. Y., has made a report on the use of the quinoformol solution in war surgery at a conference of the Research Society of the American Red Cross in France. Demonstrating the efficacy of the sterilizer, and the great advantages which had resulted from its application, he explained that it was a stable solution, easy of preparation, and could be used in an early stage of wound treatment at the field or evacuation hospital. The solution had been tested by a number of surgeons at an American Red Cross hospital on one hundred cases of severely infected wounds, mostly compound comminuted fractures, which had been treated for ten days to two weeks, or longer, with Dakin's solution, and in which the bacterial flora showed no signs of diminution in the great majority of instances.

Observations of the hundred cases showed that there was a pronounced drop in temperature and pulse in many cases on changing from Dakin's solution to quinoformol without any attendant operative procedure. Some wounds showing a count of ten to fifteen bacteria per field were apparently rendered free from germs within three days. Thirty consecutive cases treated within thirty-six to forty-eight hours after receipt of injury, in which preoperative smears were made and the presence of infection established, were rendered sterile within forty-eight hours, and continued to show absence of any bacteria on repeated counts subsequently with one exception.

From Mont-Valerien, at the end of the Bois de Boulogne, Paris spreads out in a panorama. On the eastern slope of the eminence has been located the army cemetery for the Paris district. Here are buried the American soldiers who die in the Paris hospitals. Yesterday, Lafayette's birthday, every one of the 280 graves was decorated with an American and French flag, placed there by the American Red Cross.

The cemetery has been used for only two or three months, but under an army engineer it is rapidly becoming as attractive as a cemetery can be. The engineer's efforts in this direction are helped immensely by the devotion of a large number of people who live in Suresnes, which also gives its name to the cemetery. These French people, most of them women, have adopted from one to fifteen graves; that is, they have assumed the duty of placing flowers on them and keeping them as green as the clay soil will permit. On most of the crosses is a little card, reading, "Adoptée par Madame ———," or "Entretenue par Madame ———." Vases, beadwork wreaths, many of them of very elaborate workmanship, and boxwood edgings, as well as flowers, are used to beautify the graves of the American dead. Back of the slope, and framing it, as one looks toward the cemetery from the roadway, is a fringe of

locust trees. The oldest grave in the cemetery is that of Private Boughet of the —— Infantry, National Guard, who died on March 26, 1918. Most of the dates on the plates tacked to each wooden cross are of a much later period, and the majority, as one might expect, bear the announcement that the soldier buried there was a U. S. Marine. Two of the graves bear marble slabs with the French and American colors, and the inscription, "Morts pour la Patrie," as indeed they did.

The Hotel Regina, situated at the corner of the Rue de Rivoli and Rue des Pyramides, has been taken over by the American Red Cross, and will become the headquarters of that organization in France. The new building is soon to be occupied by all the departments of the Red Cross, with the exception of the northeastern zone, which will remain at 4 Place de la Concorde. The bedrooms and bathrooms of the Hotel Regina are being converted into offices, and as soon as this work is done the departments of the Red Cross will begin moving into it. The large dining room, which will accommodate 200 persons, will be used as an assembly hall and the vast kitchens will be used for preparing cakes, candies, and ice cream, which are to be shipped to hospitals in the Paris district.

Experiments of great interest from a scientific as well as humanitarian point of view are being made at Nice on soldiers blinded in the war. M. Kann, a Polish savant, who is a soldier in the Foreign Legion, has invented an apparatus which may restore the eyesight of men blinded by an accident, and particularly of those who have lost their sight through wounds. His invention is based on the two following considerations: (1) There are no opaque bodies; that is to say, certain light rays can render objects visible through a screen; (2) blindness, even in the most serious case of enucleation of the eye, does not bring about the insensibility of the optic nerve, which, as long as it is living, remains susceptible to the influence of luminous impressions.

M. Kann has been authorized to come to Nice on special permission to carry out his experiments. He has constructed an apparatus of small volume, in the form of a mask, or half mask, which is placed on the face of the blind man, and which is connected by wires with a portable electrical induction apparatus. Lenses, total reflection prisms, a camera filtering the light rays, and phosphorescent plaques complete the apparatus. The principle of the invention is progressive reeducation, varying in period with each subject and the length of time which the blindness has existed. Gradually, in accordance with the exact prognostications of the inventor, the blind men who have been subjected to the experiment for a few hours daily have successively perceived, instead of the yellowish gray tint which habitually in their case replaces sight: (1) All the colors of the spectrum, beginning with red; (2) natural white light; (3) shadows, and then objects in this light. One of them has distinguished ordinary furniture, discriminated between two and three fingers of a hand, and indicated the limits of a well-lighted garden. These experiments have been interrupted for the moment, but are to be resumed.

A health rate that has been established by the American armies in France and back home, so far as is known, has never been surpassed. For the week ended July 26 the combined reports of the A. E. F. and of troops stationed in the United States show an annual death rate for disease of 1.8 per thousand, less than two per thousand per year. The annual death rate for disease of men of military age in civilian life is 6.7 per thousand. This new rate is based on an approximate strength of 2,500,000 men, and includes men living under abnormal conditions. The oversea record was made while American soldiers were participating in the heavy fighting in the Marne salient, when they were frequently compelled to sleep and eat under the most primitive conditions. That this record is truly representative of the general health of the troops is shown by the combined reports, which indicate the figure of 2.8 per thousand as the average death rate for disease during the past two months.

The American women physicians who have come to France with the "Women's Overseas Hospitals," under the National American Woman Suffrage Association, are making a name for themselves in France and for American women in general. The first commissions which the French government has given to American women physicians have been given to three surgeons of the Women's Overseas Hospital. Dr. Caroline Finley, Dr. Lee Edward, and Dr. Anna Sholly, who have been engaged in a French hospital at the Château d'Ognon, near Senlis, since last April, have been made first lieutenants in the French army, and this on the heels of receiving the Croix de Guerre last week. One of the nurses of the same unit, Miss McKeene, also received the Croix de Guerre. It seems that the entire unit has accomplished excellent work, its citations showing that it has been brave and courageous while performing its duties under fire. While working in a French hospital the members have been able to do a great deal for our own men, as many American wounded were received at the château during the summer.

The first unit of the Women's Overseas Hospitals arrived in France last March, and was immediately put into action by the French Service de Santé. A second unit is doing refugee work near Bordeaux, and the third unit has recently arrived in France and has been assigned to work in a French hospital for gas patients near the front. While waiting to be sent to this hospital the members of the unit are being instructed in the care of the gas patients in Paris. They have been visiting the various gas hospitals for the past few days, and expect to receive further instruction next week. Military Unit No. 1 is under the direction of Dr. Caroline Finley; No. 2, at Labouheyre, is under the direction of Dr. Marie Formad; and Dr. Marie L. Lefort is the director of No. 3 for the treatment of gas cases.

Were Columbus's Sailors the First European Syphilitics?—In *Il Policlinico* for April 14 appears a long digest of an article with this title written by Downing for the *Boston Medical and Surgical Journal* about two years ago in which Bloch's theory of the American origin of syphilis was adversely criticized. The editor while making but little comment appears to be in full sympathy with Downing's viewpoint. In addition to Bloch's failure to prove his case there is something unworthy in the attempt to dim the glory of Columbus's achievement by making him responsible for the spirochete's ravages in Europe.

4. Diseased Tonsils and Focal Infection.—Harry Rodman reports a number of cases of joint conditions resulting from focal infection due to diseased tonsils, which were greatly benefited by tonsillectomy. Removed tonsils were examined in all cases; in most of them pathogenic bacteria were found, particularly various streptococci groups, and in some circumscribed abscesses were found imbedded deeply in the tonsillar tissue and near the capsule. Tubercle bacilli were rarely met with. The preoperative administrations of vaccines did not prove to be of benefit, but the writer believes that after tonsil enucleation, if symptoms have become aggravated temporarily, they may be of use. From his own experience and that of others Rodman feels justified in recommending removal of tonsils in all patients suffering with local and systemic infection and where the tonsils are at all diseased. On the other hand, the condition of the accessory sinuses, the teeth, ears, etc., should be studied for possible forms of infection and as connecting links in the chain of causative agents in the production of painful joints and other ailments. Such conditions as pyorrhea, sinusitis, gonorrhea, syphilis, colitis, state of the entire genital tract, must be investigated, and Wassermann tests, *x*-ray examinations of the ethmoid frontal sinuses, the antrum of Highmore, complement fixation tests, etc., should be made before arriving at a definite conclusion in regard to the seat of focal infection.

3. Prophylactic Vaccinations Against Catarrhal Infections of the Respiratory Tract.—John W. H. Eyre and Captain C. E. Lowe report the results of a series of prophylactic inoculations with mixed vaccines against purulent bronchitis and respiratory catarrhs in New Zealand troops in England. In January, 1918, 327 cases of measles and rubella, all of a mild type, occurred among members of a certain reinforcement of the New Zealand Expeditionary Force, which had arrived in England on the 7th and 9th of that month. During February a further 124 cases were admitted to hospital, and of these 24 died. An investigation revealed the fact that the exanthem was usually complicated by "purulent bronchitis," clinically identical with an outbreak which occurred in the Aldershot command early in 1917. The bacteriological findings were: *B. influenzæ* was present on one or more occasions in 12 out of 14 sputa examined, usually associated with *Streptococcus longus* and various types of *Micrococcus catarrhalis*. In fatal cases the heart blood and spleen showed the presence of *Streptococcus pyogenes longus* with marked hemolytic properties. Morbid histology of pulmonary tissues consisted chiefly of a purulent bronchitis and peribronchitis associated with areas of edema, areas of collapse, and patches of lobular bronchopneumonia, while at the bases of the lungs the process tended to involve larger areas, and, in rare instances, to progress to complete consolidation. The incidence of rubella and morbilli must be regarded, therefore, in many instances as a predisposing cause producing the initial lowering of resistance which facilitated the entry of the *B. influenzæ*; in other cases the eruptive fever appeared to be merely a coincidence. The few blood counts that were made showed a slight but distinct polymorphonuclear leucocytosis, not only relative, but also absolute. Bearing in mind the susceptibility of the average New Zealander to infections of the respiratory tract, it was decided to attempt to immunize reinforcements by prophylactic inoculation against catarrhal infection, and arrangements were at once made for the vaccination of the entire personnel of the two most recent reinforcements in England. A multiple vaccine was prepared from organisms contained in the secretions of purulent bronchitis and in the sputa of other catarrhal cases among the troops in England. The vaccine was prepared in two strengths, the dosage to be 5 c.c. on each occasion, the second dose, *i.e.* the stronger vaccine, to be administered ten days after the first. The initial dose was given to 2081 men; in 97.7 per cent. there was no reaction, in 2.0 per cent. the reaction was slight, and in 0.3 per cent. severe. The number of men who received the second inoculation was 1627; in 98.8 per cent. there was no reaction, in 0.7 per cent. slight reaction, in 0.4 per cent. severe reaction. A statistical record was made of the results of vaccination in the first 1000 cases inoculated and this has been compared with the average of all respiratory complaints occurring per 1000 among uninoculated New Zealand troops in the United Kingdom from March 15, 1918, to August 18, 1918. This shows that whereas only 12 cases of respiratory complaints among the inoculated men were admitted to hospital, the average among uninoculated troops was 73.1 per 1000. Anticipating a "negative phase" as a result of inoculation, the authors arranged that all cases, however trivial, should be admitted to hospital; 15 admissions were reported between the first and second dose of vaccine, and 82 during the ten days following the second inoculation. The authors therefore suggest that the initial dose might be larger, or the interval between the two doses a few days longer. The effect of the inoculation was demonstrated in June, when a widespread pandemic of influenza commenced, the prime factor being the *B. influenzæ*, associated in severe cases with other catarrhal organisms. The incidence of this epidemic was appreciably less among the inoculated men, being 2 per 1000 as against 28.4 per average thousand. Serological tests were made in the case of 20 New Zealand soldiers both before and after inoculation and 10 English soldiers who had not received any catarrhal vaccine or suffered more than ordinarily from catarrhal complaints. The number of cases was too small to permit of much weight being accredited to the results, but it would appear (1) that the average colonial, just arrived in England, has only about 50 per cent. of the natural immunity to the organisms of catarrh prevalent in England that the average English soldier enjoys; (2) that as a result of catarrhal vaccination his immunity can be considerably increased, and (3) that, at any rate for a time, his specific agglutinins to catarrhal organisms exceed in amount those of the average Englishman.

4. An Analysis of Causes of Breakdown in Flying. With Notes on the Nervous Mechanism of the Flying Man.—Captain Norman S. Gilchrist has chosen the term "breakdown" to describe patients rejected by the Royal Air Force Special Medical Board as permanently unfit, that is unable to fly for at least six months, more probably for years, and possibly never. He points out that the great difficulty is to distinguish between nervous subjects who will not make good flyers and the highly strung, sensitive type, who is healthy otherwise and whose nerves are under control—a type who has proved over and over again the finest flyer of all. An analysis of 100 consecutive cases showed the cause of failure to be psychological or subjective, i.e. loss of confidence or general breakdown, in 67 cases; objective nervous conditions in 14 cases; and physical complications in 18 cases. A careful review of the candidate's past nervous history will give valuable information as to his fitness for duty as a flying officer. Since an unstable nervous temperament is hereditary, the family history is important, 27 per cent. of failures giving a nervous family history; a nervous personal history (40 per cent. of failures) must also be considered, and nothing leads to failure more surely than a history of a serious nervous breakdown (30 per cent. of failures). The time at which such a breakdown took place makes little difference. In the case of observers who come up for training as pilots with a history of such breakdown, certain men of unusual strength of will and character may be accepted, if there are no active symptoms and if they have had a prolonged rest since the breakdown. In the qualified pilot much depends upon the cause of the breakdown and on the individual; if due to stress of service or malaria, recovery should take place; experience, however, has shown that few stand the strain of service long enough to justify their training. Dreams, nightmare, and somnambulism in infancy resulted in 21 per cent. of failures, and in adult life in 55 per cent. of failures. Such a history is a sign of an unstable nervous system, and the author points out that even a qualified flying officer should be free from nightmare for eight or ten weeks at least before commencing to fly again. Thirty-seven of the cases gave a history of concussion or shell shock. Candidates with a history of concussion with prolonged unconsciousness should be rejected except in very special cases; if followed by nervous breakdown, every case should be rejected. This applies also to shell shock. Qualified pilots with history of concussion may be employed again after two or three months' rest, if recovery has been speedy and has not been followed by nervous breakdown. However, they should be given light duties at first with dual control. Where there has been more than one attack of concussion, very prolonged rest is necessary. As a rule both in candidates and flying officers affections of the higher cerebral functions (which occurred in over 52 cases of the series) preclude future flying; they may make capable instructors after due rest, but as pilots they do not last even if they resume flying. Thirty-six of the cases gave a history of recent malaria, and Captain Gilchrist emphasizes strongly the fact that malaria is often the direct cause of a breakdown of the nervous system and especially of the higher cerebral processes. Under rest and appropriate treatment such cases do well. Exaggerated reflexes (82 cases) and tremor (73 cases) in themselves are not of importance. In deciding whether or not to reject a candidate who is highly strung, a great deal depends upon the individual; the university athlete who has been trained to self-control will probably justify training expenses, but it is better to reject the introspective clerk with little experience of outdoor exercise or sport. Much depends also on the way in which such subjects are handled in training. They are sensitive of criticism and overanxious to do well and should be encouraged rather than found fault with. Finally, medical officers who believe that the ailments of the neurasthenic are imaginary and can be voluntarily set aside should not be attached to flying schools, where the medical problems give scope for the finest scientific minds.

6. Intravenous Saline in Blackwater Fever.—Captain Adam Patrick points out the importance of increasing the flow of urine in cases of blackwater fever, as the great danger lies in obstruction of the kidneys through deposition of brown amorphous material in the tubules. What is wanted is a rapid copious passage of water through the renal channels, which can be best obtained by intravenous injection; and this should be done before the tubules become blocked. Captain Patrick cites a case in which the patient's life was probably saved by the timely injection of sodium chloride solution intravenously, and in which recovery was rapid and uninterrupted. He notes that the textbooks on tropical medicine usually suggest giving saline solution intracellularly or by the rectum.

Berliner klinische Wochenschrift.

September 2, 1918.

Fibrin as a Means of Defense and Cure.—S. Bergel, although not offering any really new facts, shows the bactericidal and reconstructive part played by fibrin. This junction belongs to it, just as the protealific junction belongs to the polynuclears and the lipolytic junction to the lymphocytes. The protective junction of wounds is without reason often attributed to the granulation tissue which is simply the result of the cleansing action of the fibrin on the wound. Venous thrombosis is also a phenomenon of defense, quite capable of preventing generalization of sepsis. The same applies to the false membrane of diphtheria, etc. The writer also calls attention to his experiments which demonstrate the unfavorable action of fibrin on the growth of staphylococci in the autoclave.

The Cinematograph as a Means of Teaching Surgery.—Von Rothe has improved upon the various procedures of cinematography and believes in the possibility of teaching by means of films. He only cinematographs the field of operation and the operator's hands. The carbon lamps are placed outside of the operating room and the cinematographist is replaced by an electrical mechanism, the film being manipulated by the operator by means of a foot-pedal. It is thus possible to stop it at the moment of certain more important steps in the operation.

Münchener medizinische Wochenschrift.

August 27, 1918.

Deep-Seated Bullets; the Use of the Electromagnet for Their Search.—Wieting sums up the experiments carried with this procedure. From his own researches he is of the opinion that the greatest improvement so far realized is the separation of the probe from the body of the magnet. By this means one can manipulate the probe so that it can be brought almost down to a missile lodged in the depths of the brain. It is then connected with the magnet and the foreign body removed. Wieting offers other suggestions derived from experience. For instance, all the pieces of missile removed should be spread in a line in order to compare them with the number of spots shown on the *x*-ray plate. One must not forget to keep at a distance pins, forceps, etc., which might be drawn into the wound. The writer even goes to the trouble of mentioning the fact that watches are spoiled for good if they pass into the field of the magnet. A metallic operating table is dangerous, inasmuch as it may be the means of drawing the probe too deeply into the central substance; therefore a wooden table should be used. The magnet may

also be resorted to as a diagnostic measure. If it is passed over a wound of the soft parts one can see the area containing the missile rise to meet it and so guides the surgeon in his search for bullets and other projectiles.

Vascular Wounds.—W. Zehn describes a phenomenon that he has twice observed out of a total of fifty cases of arterial wounds, namely, a wound of a collateral producing a hematoma compressing the main artery. The presence of the hematoma and the absence of the peripheral pulse tend to mask the correct diagnosis inasmuch as the main artery is supposed to be involved. At operation the cleaning out of the hematoma removes the compression and the peripheral pulse returns. The writer questions how the pressure of the clot can become sufficiently strong to compress a large artery such as the femoral. He explains it by the hemorrhage itself, which tends to diminish the blood pressure as the tension in the hematoma increases from the afflux of blood from the wounded vessel.

Deutsche medizinische Wochenschrift.

August 29, 1918.

A Comparison of the Forces of the Blood Current, Theoretical and Practical.—K. Hürthle comes to a negative conclusion on this question, namely, to ascertain if forces other than the cardiac impulse play a part in the progression of the blood (arterial contractility, etc.). He bases this conclusion on the calculation of the forces necessary for this propulsion, taking into account the identity of the necessary theoretical forces with the figures derived experimentally.

The Regeneration of Striated Muscle.—A. Bier, in concluding this article, offers some more observations in support of his thesis of the possibility of regeneration of muscular tissue. Far from being nil as has been maintained too often, this regeneration may result in a more perfect reconstitution of tissue than any other type of tissue regeneration (bone for example). This fact, the practical importance of which is less than that of nerve or bone regeneration, has a considerable scientific importance. It overturns the too general axiom which maintains that tissues and organs regenerate all the more incompletely and with difficulty the greater be their differentiation. Bier, for that matter, attributes the greater or lesser power of regeneration to the presence of favorable conditions, rather than to a special disposition or faculty of any given tissue of the organism.

Treatment of Malaria by Quinine Alkaloids and Their Chemical Substitutes.—J. Morgenroth first of all is opposed to the belief that the part played by quinine is merely parasiticidal. The study of the concentration of quinine in the blood during treatment, even when intensive, shows that this is absolutely insufficient to realize such an effect. (Exhibition of quinine hydrochlorate by mouth in the dose of 50 centigrams to 1 gram, blood concentration of 1/150,000 or even less. Five minutes after an intravenous injection of the same dose the concentration is 1/20,000 or less.) The writer next puts the question as to what mechanism may be substituted for the generally accepted explanation of the action of the drug and for this purpose he takes up the relations of the quinine alkaloids with the red blood corpuscles. The writer pretends that he has been able to see the erythrocytes take up quinine and that the drug accumulates in the corpuscles. This reaction is realized *in vitro* at the same concentrations as the quinine treatment can realize in the circulating blood.

Correspondenz-Blatt fuer Schweizer Aerzte.

June 29, 1918.

Problems of Nutrition.—Silberschmidt states that the lessons of the great war on diet and nutrition are not yet obvious because there has been no opportunity to digest them. Data obtained before the war show that 51 per cent. of the protein of the Swiss people comes from milk and milk products; 24 per cent. from meat; 13 per cent. from fruit and vegetables, and about 5 per cent. each from potatoes and grain. Of fats, 68 per cent. of the whole is supplied by milk and milk products and 26 per cent. from meat, while the per cent. from grain and potatoes is negligible and about 3 per cent. comes from fruit and vegetables. Of carbohydrates 35 per cent. comes from fruit and vegetables, 24 per cent. from potatoes, 20 per cent. from milk and milk products and 18 per cent. from grain. Of calories 41 per cent. comes from milk and its products, 20 per cent. from fruit and vegetables, about 15 per cent. from meat, 12 per cent. from potatoes, and 10 per cent. from grain. Milk is therefore the mainstay of the Swiss. Next in value come fruit and vegetables. If potatoes are included under vegetables the two classes furnish nearly 75 per cent. of the total calories. The small rôle played by cereals in the diet of the Swiss is impressive. The average per capita consumption of milk and its products in that country is over 320 kilos, nearly all of this class of food being of domestic production. The average per capita consumption of bread and other dough products is less than 200 kilos and nearly half must be imported. The average consumption of fruits is 91 kilos and this class is mostly domestic in source. Of potatoes over 200 kilos per head are used, nearly all domestic. All other classes of food are largely imported and the country produces very little sugar, fats (aside from butter fats), poultry, eggs and fish. Even vegetables are freely imported. Switzerland is eminently deficient in carbohydrates and normally imports 60 per cent. of this class. After the war had cut down the imports Switzerland began to cultivate the potato more intensively. The cereal crop was also increased, but so badly off in this respect has the country been that but little headway has been possible so far. It must therefore for the present make up all carbohydrate deficit from an increased production of fruits and vegetables. The per capita consumption of alcohol is over 180 kilos and there is not the slightest hint that the making of spirits should revert to the food classes, although the whole subject of food economics is reviewed.

Correspondenz-Blatt für Schweizer Aerzte.

July 13, 1918.

Herpes Zoster Nasofrontalis with Extensive Paralysis of Eye Muscles.—Loeffler describes a case of this rare association in an old woman whose health had always been excellent. On February 28 of the present year she was attacked very suddenly with pains in the side of the head and face, which persisted and were associated with pain and redness in the eye of the same side (right). The lid became puffy and a red area appeared on the forehead upon which vesicles formed. The first diagnosis was facial erysipelas, and malaise and fever supported this view; but on the following day she was afebrile. The severe pains in the head prevented sleep and these even increased just as the redness and swelling began to clear up (after 4 days). Patient was not seen until the eighth day of the disease. The appearances were those of ordinary frontal zoster with the extension of the area down the right side of the nose until within half a centimeter of the tip. The line of demarcation in the middle of the nose was sharply drawn. There was no eruption in the nasal mucosa, but the sense of taste was somewhat disordered. The conjunctiva of the right eye was injected and there was slight chemosis, while one vesicle of herpes was present at the limbus of the cornea. The eye was now closed tightly. There was a haziness of the cornea and the pupil was rigid to light and accommodation. The cornea was anesthetic. The zoster gradually improved and left no sequelæ with the exception of the ocular peralyses about to be described. The closure of the eyelid was not due to swelling but to ptosis and the patient was also unable to turn the eyeball upward. Eventually it became evident that the eye could not be turned downward nor outward. The diagnosis finally ran as follows: total internal ophthalmoplegia and partial external ophthalmoplegia. In order to explain this localization, one must suppose a primary lesion of the Gasserian ganglion plus a secondary neuritic process in the involved motor nerves.

Increase in Births in Women Over 35.—In Hesse a larger percentage of women over 35 years of age are bearing children than was the case before the war.—*Correspondenz-Blatt für Schweizer Aerzte.*

Book Reviews.

NAVAL HYGIENE. By JAMES CHAMBERS, A.M., M.D.; Medical Inspector, United States Navy; Master of Arts in Hygiene, Johns Hopkins University; Head of Department of Hygiene, United States Naval Medical School; Professor of Preventive Medicine, George Washington University. Published with approval of the Surgeon-General, United States Navy, and by permission of the Navy Department. With 153 Illustrations. Price, $3.00. Philadelphia: P. Blakiston's Son & Co., 1918.

NAVAL hygiene is of more importance than ever before. The construction of the modern ironclad lends itself, in some degree, to insanitation. Space is more limited by far than in the roomy old wooden three-deckers, and the materials used in the building of the up-to-date dreadnought renders it necessary that particular care be paid to introducing the best hygienic methods possible. In "Naval Hygiene" Dr. Pryor deals with the entire subject at length, not only so far as the navy is concerned but with the hygiene of merchantmen also. The work is peculiarly appropriate at the present time.

NURSING IN DISEASES OF CHILDREN. By CARL G. LEO-WOLF, M.D.; Chief of Clinic for Sick Babies and Children for the Health Department of the City of Buffalo, N. Y.; Instructor in Pediatrics, University of Buffalo, Medical Department; Author of "The Child in Health and Sickness." With 72 Illustrations. Price, $2.50. St. Louis: C. V. Mosby Company, 1918.

IT would be superfluous to elaborate on the vital importance of pediatrics at the present time. The fact must also be taken into consideration that in the successful rearing of a child good nursing—that is, scientific nursing—is the primary factor. But the good nurse is not like the poet, "born and not made." She has to be instructed and trained in the art of scientific nursing. Dr. Leo-Wolf has written this textbook with the view of so instructing the nurse and appears to have succeeded well in his object. The book is excellently illustrated.

HYGIENE FOR NURSES. By NOLIE MUMEY, M.D.; Lecturer in Hygiene, Chemistry, and Bacteriology, Logan H. Roots Memorial (City Hospital) Training School; Assistant Instructor in Surgical Technique, University of Arkansas; Resident Physician of City Hospital and a Member of the Visiting Staff, Little Rock, Arkansas. With 75 Illustrations. Price, $1.25. St. Louis: C. V. Mosby Company, 1918.

THIS is a small volume, containing superficial instruction on hygiene. For those who know nothing of the subject, the book may prove of some use. Many of the statements are inaccurate or misrepresent the truth, and the illustrations take up much valuable space. Among the curiosities of information presented for the instruction of nurses we find: "In the male (infant) a long adherent prepuce with adhesions may cause convulsions or enuresis. The glands should be retracted and anointed with vaseline until the adhesions disappear"; "Eugenics does not mean infanticide." The statements that "in tertian malaria the paroxysms occur every third day, and in quartan they occur every fourth day," are liable to be misunderstood. Misprints are numerous: "Koplick's spots," "Pfeifer bacillus," "Aeds colopus," "Glossina polpolis," "Opthalmia,' "cassion's disease," should be corrected.

A TEXT-BOOK OF ELEMENTARY MILITARY HYGIENE AND SANITATION. By FRANK R. KEEPER, A.M., M.D., Colonel, Medical Corps, United States.; Formerly Professor of Military Hygiene, United States Military Academy, West Point. Second Edition, Reset. Price, $1.75. Philadelphia and London: W. B. Saunders Company, 1918.

THIS is the second edition of the very useful text-book on military hygiene written by Colonel Keeper and published in 1914, just previous to commencement of the Great War. It has been thoroughly revised, a revision rendered necessary by trench warfare and by other innovations in modern methods of fighting. The book covers the entire subject, is written in concise, plain language and is admirably adapted for instruction of army officers and men as well as for others who are engaged in work behind the lines and in camps at home.

MEMORANDA ON ARMY GENERAL HOSPITAL ADMINISTRATION. By Various Authors. Edited by P. MITCHELL, M.D., Aberd. Lieut. Colonel R. A. M. C. (T.F.); Officer Commanding No. 43 General Hospital. Price, $2.25. New York: Paul B. Hoeber, 1918.

THIS volume contains but little more than a hundred pages and, save for a few diagrams, is quite free from illustrations. The subject should be rather trite by this time, and we fail to see the necessity for a new work of this character and size. The individual chapters deal with the officers, the coördination between the civil and military authorities, the nursing service, kitchens and cooks, medical division, surgical division, camp sanitation, clerical service, etc.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia. Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. September 1, 1918. Price, $6.00 per annum. Philadelphia and New York: Lea & Febiger.

THE first eighty pages of this volume contain a review of diseases of the thorax and its viscera, including the heart, lungs and bloodvessels, by W. Ewart. Gottheil's review of Dermatology and Syphilis is, as usual, complete and interesting. The section on Obstetrics, by E. P. Davis, is the longest in the volume, and contains a valuable summary of the recent work on the relation of the glands of internal secretion to obstetrics. The final paper is by W. G. Spiller, on Diseases of the Nervous System. The volume is smaller than usual, probably on account of the scarcity of paper.

PRACTICAL BACTERIOLOGY, BLOOD WORK, AND ANIMAL PARASITOLOGY. Including Bacteriological Keys. Zoological Tables and Explanatory Clinical Notes. By E. R. STITT, A.B., Ph.G., M.D., Medical Director, U. S. Navy; Commanding Officer and Head of Department of Preventive Medicine, U. S. Naval Medical School; Graduate, London School of Tropical Medicine; Professor of Tropical Medicine, Georgetown University; Professor of Tropical Medicine, George Washington University; Lecturer in Tropical Medicine, Jefferson Medical College; Member, National Board of Medical Examiners; Member, Advisory Board, Hygienic Laboratory; Formerly Associate Professor of Medical Zoology, University of the Philippines. Fifth edition. Revised and enlarged. With 1 plate and 144 other illustrations containing 598 figures. Price, $2.00. Philadelphia: P. Blakiston's Son & Co.

THIS little book is well known as a work of sterling merit. The author has succeeded in giving the busy student and practitioner the necessary information on the subjects handled in this volume, and has wisely omitted all padding and non-essentials. In this new edition the author has added paragraphs on the agglutination of meningococci and pneumococci; the Dreyer method for interpretation of agglutination reactions of typhoid and paratyphoid infections has also been given in the section on immunity; a new chapter on poisonous arthropods and fishes has been added; new material, including preparation of Dakin's solution, has been added to the section on disinfectants; delousing methods are included; a brief presentation of Mosenthal's nephritic test diet method of studying renal functioning will be found in the section on urine.

INTERPRETATION OF DENTAL AND MAXILLARY ROENTGENOGRAMS. By ROBERT H. IVY, M.D., D.D.S., Major, Medical Reserve Corps, United States Army, etc. Price, $2.50. St. Louis: C. V. Mosby Co., 1918.

THIS volume is an atlas of 259 illustrations, comprising in addition to roentgenograms numerous photographs and microphotographs. In addition to interpretation of radiograms, chapters are devoted to anatomy, pathology, clinical findings and the techniques of roentgenography, all of these sections leading up to the subject of interpretation, which constitutes the second part of the work.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-eighth Annual Session, Held at Philadelphia, September 23, 24, 25, and 26, 1918.

First Day—September 23.

DR. WALTER F. DONALDSON OF PITTSBURGH IN THE CHAIR.

President's Address: Medical Activities in Pennsylvania.—Dr. FREDERICK L. VAN SICKLE, the president-elect, delivered this address. Attention was called to the fact that for the first time in the history of the Medical Society of the State of Pennsylvania the society had sustained in the death of Dr. Samuel G. Dixon the loss of a president during his term of service. An earnest tribute was paid to the late president whose influence upon medical and civic affairs had been much beyond that possible to the average member of the profession; and the hope was expressed that the work established by Dr. Dixon might be fully continued. Emphasis was placed upon the outstanding duty of the medical profession to become organized in either the Medical Reserve Corps, or the Volunteer Medical Service Corps. The desirability of the creation of a commission in the society for correlation of work with the War Department was urged. Social insurance was shown to need the help of all thoughtful workers in this field; closely allied to such question was the matter of physical examinations that the industrial worker might be kept fit. Greater business acumen, it was also suggested, should obtain in the medical profession. The plan of the president of the American Medical Association relating to the supply of medical men was endorsed for adoption by colleges. President Van Sickle felt that the time had long since passed when there should be demanded of the Federal and State governments legislation eliminating the manufacture and sale of alcoholic beverages, not merely as a war measure, but for all other known reasons.

Interpretation of the Manifestations of Shock.—Dr. C. C. GUTHRIE of Pittsburgh recommended that the term shock be reserved for the condition exemplified by the acute clinical state; and that the term collapse be employed to designate the moribund state following shock or any other condition. Experimental evidence was presented supporting the probability that the primary derangement in shock is of nervous character. In collapse, indirect and general considerations, it was said, indicate profound nervous derangement; the conditions in shock and collapse differ fundamentally and treatment indications differ accordingly. In shock associated with severe hemorrhage restoration of blood volume was indicated. For this purpose transfusion seemed best, but beneficial action might be obtained by intravenous injections of artificial solutions. The addition of a colloidal substance to such solutions was said to cause their longer retention. For this purpose dilute acacia was preferable to other substances hitherto employed. Preventive measures and prompt treatment were regarded as strongly indicated. Preventive measures were omitted from the discussion from lack of adequate first hand observations. Discussion of theories was omitted for the reason that at the present time they are legion and no one has overwhelming support.

Surgical Shock in Face Mutilations and Coincident Injuries.—Dr. JOHN B. ROBERTS of Philadelphia said that "shock" was used to cover many symptoms following injury such as anemia, fat embolism, rapid absorption of septic fluids, rapid abstraction of heat from abdominal organs. Porter's conclusions relative to fat embolism, enforced inhalation of carbon-dioxide, in Dr. Roberts's opinion, were apparently largely founded upon examination of cases many hours after injury. Lowering of the alkali reserve in the blood after anesthesia and operative attacks, and the beneficial effect of intravenous use of alkaline solutions, it was said, seemed to indicate a possible relation between shock and acidosis. Avoidance of fall of blood pressure, prevention of pain, and control in severity of traumatism were enumerated as essential to prevention of shock. Treatment required that the blood pressure of the wounded be raised above the critical point. Elevation of the feet and intravenous injection of saline solution would raise diastolic blood pressure to 70 or 80 mm. Adrenalin might be used in addition if the pressure again fell. When gravity exerted by elevating the feet and trunk retained the blood pressure at 75 or 80 intravenous medication might be stopped. External heat was mentioned as of highest importance. Pressure should be made upon the wound and not by tourniquet above wound. Frequent blood pressure examinations were regarded as of great value as a guide. Geoffrey Marshall's objection to morphine was regarded by Dr. Roberts as probably an unwise opinion and founded upon anesthetic observations rather than upon the study of clinical surgery as an operating surgeon.

Dr. S. J. MELTZER of New York said he would first take up the theory of acapnia. It assumed that shock was due to a diminution of CO_2 in the blood of patients in shock. This assumption suggested at the same time the treatment which consisted in letting the patient breathe some carbon dioxide, or respire through a long tube or, as it was called for short, rebreathe. The theory of acapnia as the cause of shock was about ten years old; it was brought forward by Dr. Yandell Henderson. If the statement that CO_2 of the blood was decreased in shock were generally confirmed, the fact of the reduction of CO_2 could not prove the correctness of the acapnia theory. The reduction of CO_2 might be merely a *consequence* of shock and not the *cause* of it. A successful treatment of a disease by a method which was devised upon a certain assumption of the nature of the cause of the disease, never proved that the assumption was necessarily correct. Geoffrey Marshall, an expert anesthetist, was of the opinion that rebreathing was a rather dangerous procedure and surely ought not to be used in shock patients. Acapnia and rebreathing died hard but, so far as the science of physiology was concerned, they were surely dying. Then the speaker discussed another phase in the physiology of shock. Low blood pressure was a predominant symptom of shock. For at least six decades physiologists firmly believed that low blood pressure was accompanied by a relaxation of the peripheral small blood vessels which caused the accumulation of the greater part of the body's blood in the vessels of the abdominal viscera. In recent years the assumption gained the ascendancy that in shock the peripheral blood vessels were contracted. Surgeons had stated that they had never found the vessels of the abdominal viscera to be engorged in shock. In England and in France Dr. Cannon had occasion to study shock experimentally as well as clinically. He became converted to the theory that the most essential factor in the production of shock was acidosis and began to advocate the treatment of shock by the administration of bicarbonate of soda. Recently the theory of acidosis as the primary cause of shock had lost ground. Bayliss himself gave up the idea that acidosis was of primary importance and he, as well as others, lost faith in the value of the alkaline treatment of shock. Dr. Meltzer then spoke of the theory that shock was produced by pulmonary fat embolism, which had received a great deal of popular attention. The article of Professor Porter in the *Atlantic Monthly* read indeed like a novel. The sentences were crisp and the style and manner of presentation were most attractive. But in science and in practice of medicine we were more interested in the truth and the practical value of the facts than in the beauty of their presentation. There was much in Dr. Porter's statements which we might readily accept. No doubt there were cases in which fractures of the long bones or injuries to fat tissues led to pulmonary fat embolism, and to a dangerous and even to a rapidly fatal fall of blood pressure. But these facts were in no way new. Dr. Porter himself admitted that shock brought about by injuries to the abdomen might be due to "change in the hydrostatic conditions of the circulation" in the abdomen and not to fat embolism. Fat embolism, a grave condition, presented a number of definite clinical symptoms outside of the presence of low blood pressure. There were, in the first place, symptoms which pointed directly to the lungs as the seat of trouble. The patient was suffering from air hunger, dyspnea; pul-

monary edema and even hemoptysis were frequently present. On auscultation the presence of rales might be discovered. Then there were indications of the presence of fat in the circulation in abnormal quantities. The urine contained fat globules. Fat might be readily detected in a drop of blood. Moreover, even the sputum might reveal the presence of fat. There were then many clinical signs which suggested that the shock-like condition of the patient was due to pulmonary fat embolism. Dr. Porter did not mention in his articles that he had availed himself of these signs. He recommended the inhalation of carbon dioxide for the treatment of shock and claimed that he had helped many such cases by this treatment. He administered carbon dioxide not for the purpose of meeting the possible exigencies of acapnia, but for the purpose of producing deep inspirations, which would help "drive the blood from the engorged abdominal veins into the chest, where it shall fill the half empty heart and permit the faithful organ to fill the capillaries." Wiggers had said that if the circulation from the right ventricle was impeded by capillary emboli in the lungs, the introduction of larger quantities of blood in the right ventricle might lead to the dilatation of that ventricle and to death. According to Wiggers, shock was distinguishable from pulmonary fat embolism by the difference of the pressure in the right ventricle and the pulmonary artery; in pulmonary fat embolism the pressure was rather high, while in shock it was low. Therefore, while in shock it was advisable to drive, by any effective methods, the blood from the veins of the abdominal cavity into the right ventricle, this procedure had to be avoided in cases of pulmonary fat embolism.

War and the Child.—Dr. Samuel McC. Hamill of Philadelphia here regarded the child as a part of the problem of the great war. Every warring nation at the end of the first year of war had discovered that their neglect of the problem of the civil population meant an enormous increase in infant mortality. As a result of governmental health agencies then instituted infant mortality in 1916 attained the lowest point known in the history of England. Coincident with this similar efforts had been applied to the needs of the various countries, neglecting no period of life. Pennsylvania, the first State to include child welfare in its war program, had established a Division of Child Welfare in its Committee of Public Safety. To establish a country-wide provision for the welfare of the children of the nation the Women's Committee of the Council of National Defense had organized a Division of Child Welfare and entered into co-operation with the Children's Bureau, to act as the agent of the Bureau in the organization and direction of child warfare in the various States through the medium of the State divisions of the Woman's Committee. To meet the full measure of success the author believed that child welfare work must have the active support of the medical profession, the fight for the children against ignorance, poverty, crime, and intemperance being essentially that of the doctor.

Reeducation of the Injured Soldier.—Major R. Tait McKenzie of Philadelphia stated as conditions which must be treated in the wounded soldier: Injury to peripheral nerves, scar tissue, post-operative conditions; functional neuroses, conditions variously grouped under "shell shock," the "soldier's heart"—but a symptom of over strain; debilities. The majority of men in war hospitals and convalescent homes, it was said, must depend for most of their present treatment and for their future efficiency upon the masseuse, the practitioner of electro- and hydrotherapy, the physical instructor and the teacher of vocational training. The course usually followed was described as beginning with preparation by heat either wet or dry, or produced by electricity, followed by stimulation of nutrition by massage and passive movement, with simple exercise taken voluntarily and eventually skilled movements by gymnastics, games, and handicrafts, graduating into industrial training. A description of the treatment of the various disabilities with an enumeration of corrective appliances was given.

The Cardiovascular Problem in the Aviation Recruit.—Dr. James I. Johnston of Pittsburgh gave his impressions from examination of candidates for the aviation corps. The high quality of the recruit physically and his splendid spirit merited the greatest admiration. The greatest apprehension among candidates for all service of fear of refusal was particularly true of the aviators. Of between eight and nine hundred men about fifty per cent. had been passed as physically fit, though only 30 per cent. had been finally accepted. In the cardiovascular group of approximately one hundred the analysis was confined to the domain of physical diagnosis. With McKenzie it was believed that murmurs in themselves have little significance. The largest number of murmurs observed were due to thyroid toxemia and were in a state of either fine balance or in unbalance. No man with a constantly systolic pressure above 135 was accepted.

New Medical Conditions and Developments in Previously Recognized Complaints Due to War Emergency.—Dr. James M. Anders of Philadelphia emphasized the increasing importance of the new medical developments from the war. Vincent's angina was mentioned as having a greatly increased incidence. Vaccines were mentioned as useful in treatment; the immoderate use of tobacco was to be avoided. The mortality in empyema due to the streptococcus hemolyticus was quoted as not less than 75 per cent.; in that due to the pneumococcus, recovery was the rule. The most approved treatment was aspiration repeated as necessary and intrapleural disinfection with Dakin's solution. Prophylaxic vaccination against pneumonia with hemolytic streptococcus and pneumococci Types I and II was advised. In Dr. Anders' opinion the examiner of recruits should rely quite as much upon a history, presence or absence of fever, the pulse, detection of bacilli in the urine and of antibodies in the blood as upon the physical signs and *x*-ray findings. Tubercular lesions should be searched for in all other organs than the lungs. Tests to exclude from military service those with latent tuberculosis could not be too stringent. Epidemic cerebrospinal meningitis necessitated early diagnosis and prompt serum treatment. The treatment of trench nephritis did not differ from that of acute glomerular nephritis in civil life. While prognosis was good in trench fever, anemia and disordered action of the heart were apt to follow in the severer forms. War edema was said to occur among prisoners of all nationalities fed on German rations. Treatment consisted of rest in bed with a diet of sufficient protein and of at least 100 grams of fat daily.

Dr. Thomas McCrae of Philadelphia believed that cases of disturbed heart action formed a troublesome problem for medical men of the Army. In such cases he felt that infection played a very small part, the overwhelming factor being the nervous element. While tobacco might not be the original cause of disordered heart action it was largely responsible for its aggravation. The difficulties encountered with the tobacco problem in the army were obvious. In war nephritis the persistence of hematuria called for particular attention. That men had been sent back from the French front line with the mistaken diagnosis of tuberculosis he regarded as no reflection upon the diagnostic ability of French surgeons. The men had lost weight, acute bronchitis with bloody sputum was present and accurate diagnosis without time for observation was scarcely possible. The probability was suggested that for two years physicians would be encountering medical conditions the result of the war.

The Fixed Full-Time Staff in the Organization of the Small Hospital.—Dr. Harold L. Foss of Danville presented the advantages of the permanent salaried staff, particularly in its application to the rural hospital. Salary versus the fee plan was considered, as were also organization of departments, concentration of authority and responsibility. The relationship of such an organization to the general practitioner, fees and the handling of benevolences were considered and a description given of the working out of such a plan at the Geisinger Memorial.

Some Blood Changes in Rats on Cancer Inhibiting and Cancer Stimulating Diets.—Dr. Ellen P. Corson-White of Philadelphia gave the effect of these diets on the blood and on (1) growth and nutrition of rats; (2) takes, growth energy, and metastases of the experimental tumor; (3) length of life of animal after inoculation. All diets giving in normal animals an approximately normal growth curve, grew large tumors with

high percentage of takes; all diets depressing the growth curve, retarded or prevented tumor growth. A study of the blood of rats on these diets showed no change in numerical count of red and white cells, but a decrease in number of lymphocytes in all diets stimulating cancer growth, and an increase in all diets which retarded tumor growth. It would appear that cholesterol was a factor which, while of little or no nutritive value, favored tumor growth when conditions favorable to its initiation were present.

Second Day, Wednesday, September 25.

DR. B. FRANKLIN ROYER OF HARRISBURG IN THE CHAIR.

Follow-Up System of the Pennsylvania Department of Health for Former Tuberculous Patients.—Dr. KARL SCHAFFLE of Harrisburg read this paper, describing the follow-up system of the Pennsylvania Department of Health for the tracing and reporting of patients discharged from the State sanitoria and dispensaries. The system differed from most of the plans in operation for such purposes, in the method employed and in the number and character of the reports obtained. The method consisted in actual face-to-face inquiry and inspection of the former patient by the dispensary nurse who had been intimately acquainted with his physical condition and economic status during his enrolment as an active case. One hundred and thirty nurses carried on these special investigations throughout the State, in addition to their supervision of the home care of those in regular attendance. Such follow-up visits were made for a period of two years after the patient's discharge, at intervals of six months.
